My interpretation of all these degeneration observations is that microneurones do not suffer significant retrograde degeneration, but do suffer substantial disuse atrophy within about ten years if widely isolated from surviving

macroneurones. Hassler[4] judged that his "thalamic internuncial cells" in the human dorsomedial nucleus, indistinguishable in his Fig. 14 from my "microneurones", suffer equal retrograde degeneration with the "specific" neurones after substantial cortical removals, but relatively less after very restricted lesions; and surmised that they project 'unspecifically' to the cortex. It may be that the tempo of degeneration is higher after wide cortical damage than after standard leucotomy; but in my judgment at least the majority of microneurones are wholly intrathalamic 'interneurones', susceptible to disuse atrophy rather than to retrograde degeneration, and I would still predict that they will be found to constitute structural essentials to the brain's attention-focusing mechanism, as well as to its electroencephalographic alpha-rhythm[1].

Reversal of Solubility Characteristics of 'Luxol' Dye-phospholipid Complexes

'LUXOL' fast blue *G* (Du Pont), the diarylguanidine salt of a sulphonated azo dye, forms complexes stoichiometrically with phospholipids[1]. These complexes have been found to be insoluble in a varying pattern in the lower alcohols. For this study phospholipid-dye complexes were prepared with the same dye and phosphatidyl choline, phosphatidyl serine, phosphatidyl ethanolamine, phosphatidyl inositol, or sphingomyelin. The complexes were produced by bringing together the dye and phospholipid in pyridine solution. After evaporation of the solvent, excess uncomplexed dye or phospholipid could be removed by the alcohol in which the complex was insoluble. The solubility of the complexes in methanol, ethanol, isopropanol and isobutanol was determined. The results are summarized in Table 1. It was found that the complexes were soluble to the extent of at least 0·1 per cent or else were completely insoluble in the alcohols used. When alcoholic solutions of dye and phospholipid were mixed, precipitates were formed in those alcohols in which the particular complex had been found to be insoluble. The absorption maximum for the dye alone in the alcohols used is 597 mμ. When alcoholic solutions of the dye and phospholipid were mixed, the absorption maximum dropped to 570 mμ before precipitation took place. If the precipitate was then centrifuged and the deposit redissolved in methanol or an alcohol in which it is soluble the absorption maximum was found to return to 597 mμ. This can be taken as evidence of dissociation where complexes are marked soluble in Table 1.

With the foregoing *in vitro* data as a guide, we tried to devise a method for the differentiation of phospholipids in tissue sections. Only partial success was achieved. In sections of brain tissue some differential staining of the phospholipids present was accomplished when solutions of the dye in the various alcohols were used. However, in other tissues some non-phospholipid material was stained. Tryptophan, present in the necrotic areas in livers of experimental animals, stained intensely with the dye in isopropanol solution. In methanol the dye stained neither phospholipid nor tryptophan but collagen and elastin were stained selectively. Frozen unfixed tissues were employed with similar results.

The dye 'Luxol' fast blue *G* is not a specific histochemical reagent for phospholipids, but its staining affinities for certain tissue components vary with the solvent used. This may explain some of the anomalous staining of phospholipids found in the literature. Recently, Wolman[2] found that the affected neurones in three cases of Neimann–Pick's disease were not stained by 'Luxol' blue; whereas Baker's procedure for phospholipids was positive. Current 'Luxol' blue techniques utilize ethanol as the dye solvent, and from reference to Table 1, it will be seen that sphingomyelin does not form insoluble complexes with 'Luxol' fast blue *G* in this alcohol. As an increase in sphingomyelin storage can be expected in Neimann–Pick's disease, the *in vitro* data furnish a possible explanation for the non-staining of the affected neurones by 'Luxol' blue dissolved in ethanol.

RADIOBIOLOGY

Effect of Multiple Injections of Calcium Compounds on the Survival of X-irradiated Rats

A MODERATE increase in the survival of X-irradiated rats has been observed when either parathyroid extract or ethylenediamine tetraacetate (EDTA) was injected before or after mid-lethal doses of X-rays[1–3]. The action of these substances has been attributed to bone resorption, which was thought to protect the adjacent radiosensitive bone marrow by exposing it to an increased concentration of newly-released calcium. In the work recorded here, we have tested this view directly by the injection of calcium compounds.

Adult males of a hooded strain of laboratory rat, weighing between 270–340 g, were used. Calcium was administered intraperitoneally as the acetate (0·12 M), lactate (0·12 M), or gluconate (0·067 M). The sodium salt of each of these compounds was also tested and administered in twice the molar concentration so that an equivalent amount of anion could be given in the same volume of fluid. All compounds were dissolved in a Krebs–Ringer salt solution[4] without phosphate buffer. The radiation source was a Philips constant-potential X-ray machine operated at 300 kV and 10 m.amp (half-value layer, 1·14 mm copper), with a target-object distance of 80 cm and a dose-rate in air of approximately 34 r./min. All rats received a whole body dose of 740 r. The animals were exposed 12 at a time in a revolving, partitioned, 'Lucite' cage. Each group of 12 consisted of 4 control animals (injected with Krebs–Ringer solution only), 4 animals injected with the sodium salt, and 4 animals with the calcium salt of the compound under investigation.

Table 1. SOLUBILITY OF 'LUXOL' DYE-PHOSPHOLIPID COMPLEXES

Dye or dye complex	Water*	Methanol	Ethanol	Isopropanol	Isobutanol	Pyridine
'Luxol' fast blue G	Insoluble	Soluble	Soluble	Soluble	Soluble	Soluble
Phosphatidyl choline—dye complex	Soluble	Soluble	Insoluble	Insoluble	Insoluble	Soluble
Phosphatidyl serine—dye complex						
Phosphatidyl inositol—dye complex						
Phosphatidyl ethanolamine—dye complex	Soluble	Soluble	Soluble	Insoluble	Insoluble	Soluble
Sphingomyelin—dye complex	Soluble	Soluble	Soluble	Insoluble	Soluble	Soluble

* *p*H 7·0

Multiple injections were used to prolong the circulating concentration of the injected materials. The toxicity of the calcium compounds was a limiting factor, but 3 injections spaced 30 min apart were found to be non-toxic in the concentrations used (exception to this was afterwards found with post-irradiation treatment (see Table 1)). Consequently, in pre-irradiation treatment the solutions were injected 60, 30 and 5 min before X-irradiation, and in post-irradiation treatment injections were given 5, 30 and 60 min after X-irradiation.

The three calcium compounds tested, either before or after X-irradiation, were seen to produce a moderate increase in survival (Table 1). In two cases, that is, calcium lactate and calcium gluconate injected after X-irradiation, the increase in survival was apparently not specific for the calcium moiety, since injection of sodium lactate and gluconate also produced a similar increase in survival. In three cases, however, that is, pre- and post-irradiation treatment with calcium acetate and pre-irradiation treatment with calcium lactate, calcium appeared to be responsible for the enhanced survival. This effect of calcium is quantitatively comparable with the effects previously observed with parathyroid extract and EDTA, and supports the possibility that calcium is involved in the protective activity of these substances.

Table 1. Effect of Multiple Injections of Calcium Compounds on the Survival of Rats irradiated with 740 r. of X-rays

Test compound	Dose* (m.moles/kg/injection)	Time of injections† (before or after irradiation)	No. of 30-day survivors / No. used: Control (salt solution)	Sodium compound	Calcium compound
Calcium acetate	0·40	B	12/48	13/48	22/48‡
Calcium acetate	0·40	A	15/48	13/48	25/48‡ (7)§
Calcium lactate	0·40	B	15/48	13/48	25/48‡
Calcium lactate	0·40	A	9/48	19/48‡	19/48‡ (4)§
Calcium gluconate	0·67	A	10/48	19/48‡	24/48‡

* Twice as much of the sodium salt of each compound was given I.P. as that indicated for the calcium salt (see text).
† Each animal received three injections either at 60, 30 and 5 min before (B) or 5, 30 and 60 min after (A) irradiation.
‡ Significant ($P < 0.05$; chi-square) using only internal controls.
§ Indicates No. of deaths from calcium injection within 2 days after X-irradiation, apparently from potentiation of toxicity by X-rays.

Two other substances which may involve calcium in their protective action and which have not previously been mentioned[2] are inorganic condensed phosphates and magnesium sulphate. Condensed phosphates, which have recently been demonstrated as protective agents in mice[5], are known to form stable complexes with calcium and in some cases to produce hypocalcemic effects[6,7]. Magnesium sulphate, which has been reported to protect X-irradiated mice and rats[8,9], is known to cause bone resorption[10]. It is possible, therefore, that condensed phosphates could function as chelating agents similar to EDTA and that magnesium sulphate could act through its osteolytic action.

An effect of calcium on cell membrane permeability and the stability of chromatin material has been considered as an explanation of its action against radiation[2,3]. Recently, calcium has been found to reduce the erythrosin staining of X-irradiated thymocytes *in vitro*[11]; this might be interpreted as a prevention of change in membrane permeability. On the other hand, the role of calcium in chromatin stability may be supported by the recent finding that X-rays break the bonds between deoxyribonucleic acid and its protein and that this damage to the deoxyribonucleoprotein complex can be reversed by the addition of calcium ions[12]. This latter may be related to the chromatin condensing action of calcium and explain in part the reason that calcium prevents post-irradiation mitotic delay in cultures of *L* mouse fibroblast[13].

Since the action of parathyroid extract and EDTA, and possibly other substances, may function in animals through bone resorption, the release of organic constituents from bone should be considered as well as a release of calcium. In this respect, chondroitin sulphate, a possible product of bone resorption[14], has been reported as a radioprotective agent[15]. Although the release of organic constituents may be involved, the evidence at present would suggest an action of calcium as the most likely possibility.

Induction of Mutations in Barley with Ultra-violet Radiation

Utilization of ultra-violet radiation (wave-length 2600 Å) for induction of mutations in higher plants has been limited to irradiation of pollen[1–3], in view of the low penetrating ability of this radiation. Though seed treatment with ultra-violet radiation had not been found effective, pre- or post-treatments with X-rays have been found to decrease or increase X-ray-induced mutation rate (depending on the X-ray dose) in hexaploid wheat[4,5] and oats[6]. From these consistent results, it was obvious that some effects of ultra-violet radiation were recoverable in spite of its low penetrability in seeds. Hence, it was decided to examine whether mutagenic response to ultra-violet alone could be enhanced by appropriate pre- and post-treatments.

To facilitate maximum penetration, naked barley seeds (var. *CN*. 292), in which the embryos are situated in the periphery, and thus easily accessible to treatments, were used. An ultra-violet germicidal lamp, with a maximum output (86 per cent) at wave-length 2537 Å, was used. The seeds were irradiated in monolayer arranged with the embryos facing the source at a distance of 15 cm. The maximum increase in temperature due to treatment was found to be 2° C. Soaking of the seeds in water for 4 h in room temperature (22° C) and oxygen saturation of seeds by subjecting them to high oxygen pressure of 70 atmospheres for 4 h were given as pre- or post-treatments. Ultra-violet treatment inhibited growth of seedlings to an extent of 27 per cent of the control at 7-day-old stage, which, however, recovered to normal condition later. No chromosomal aberrations were recorded in any of the treatments except for stickiness. The X_1 plants were gathered individually and the chlorophyll mutations were scored in the X_2 generation. The results are presented in Table 1. *albina*, *tigrina*, *xantha* and *viridis* were the types of chlorophyll mutations recorded.

Pre-treatment of oxygen is effective in increasing the mutation rate of ultra-violet, whereas post-treatment with oxygen has no effect. This implies that oxygen during treatment is essential for the enhanced effect. With our method of oxygen saturation, the oxygen becomes bound to the seeds in a way that it is very difficult to remove by evacuation[7]. The oxygen effect during ultra-violet irradiation has been demonstrated in several aqueous systems like DNA in solution[8]. It is known that the action

Table 1. Frequency of Chlorophyll Mutations in X_2 Progenies of Barley Seeds, Irradiated with Ultra-violet Radiation

Treatment	No. of X_1 families studied	% of families segregating for mutations	No. of X_2 plants scored	% of X_2 plants mutated
Control	135	0	9,722	0
Oxygen pressure (4 h)	50	0	3,450	0
Ultra-violet (4 h)	80	2·5	6,042	0·07
Oxygen—4 h + ultra-violet 4 h	65	6·2	4,262	0·14
Ultra-violet—4 h + immediate oxygen saturation	60	0	4,560	0
Soaking in water—4 h + ultra-violet (4 h)	127	7·1	7,877	0·35

of ultra-violet light is mainly through the excitation of the molecules and this may set in a prolonged free-radical reaction in the presence of oxygen[9]. This may be the probable explanation for the enhanced effect of ultra-violet light in the present case. Such reactions are short-lived and hence are not available for post-irradiation oxygen effect, unlike X- or γ-irradiated barley seeds, which respond to post-irradiation oxygen treatment[10]. The increased effect of ultra-violet light on soaked seeds appears to be due to one or more of the following three causes: (1) a better penetration of ultra-violet light in hydrated systems[9]; (2) the initial metabolism set in the seeds due to soaking, making them a more susceptible system; (3) the effects of ultra-violet light on water molecules which are in excess in soaked seeds and which can act indirectly on the genetic material. The failure to induce mutations with ultra-violet irradiation alone in hexaploid wheat[4,5] may be attributed to its high polyploid nature as well as the chromosomal origin of most of the induced mutations in this crop.

In vivo Investigation of the Removal of Trace Elements from Nucleic Acids of Yeast by Ionizing Radiation

Investigations by several authors[1,2] have demonstrated that paramagnetic metal ions produce a certain amount of resistance to radiation in cells. This fact is due partly to the redox effect of these ions[3], and partly to the facilitation of forbidden transitions of excited electron states[4]. Since different nucleic acids contain trace elements in significant amounts[5], and since the biological activity of nucleic acids is dependent to a large extent on their trace-element content[6–8], it seemed essential to us to investigate the trace-element content of those most important macro-molecules of the cell before and after irradiation. It was also shown that by roentgen irradiation removal of Ca^{++} and Mg^{++} from nucleohistone is possible, whereby at the same time reduction in DNA occurs[9].

Determinations of the trace-element content were carried out by means of neutron activation analysis[10]. The removal of trace elements from nucleic acids was determined between 0 and 24,000 rads of cobalt-60 irradiation. Part of the trace elements was detected in the low molecular cell fraction after irradiation in this dose-range. Another part might be bound by metal binding molecules, or else might be re-bound at ionizing points caused by the irradiation. In this way the decrease of the trace element content at doses above 8,000 rads could be explained. Yet it seems that in the investigation range of dose no diffusion of trace elements occurs through the cell wall owing to changes in permeability.

Yeast was suspended in aqua bidest., and air was bubbled through for 5 h. For the irradiation carried out at 23° C the centrifugated yeast was re-suspended in aqua bidest. (20 ml./g yeast). Thon the yeast was centrifugated (distribution of trace elements in this centrifugate is given in Table 3), the low molecular compounds were extracted with 60 per cent ethanol and the nucleic acids with 1·0 M ammonium formate as recently shown[11].

Table 1. Trace Element Content (μg Ions per Sample) of Nucleic Acid of Yeast after Different Irradiation Doses (Mean Value of Six Different Cultures)

Dose (rad)	Cu	Mn	Ni	Zn	p
0	30·1 ± 3·0	5·9 ± 1·2	32·3 ± 6·0	130 ± 27	3,870 ± 190

The metal ions liberated from nucleic acids may cause a diminution of the biological activity of the macromolecules (eventual change of the tertiary structure). Moreover, they may cause slight damage (early stages) to the cell by operating as inhibitors or stimulators of enzyme systems[12].

BIOLOGY

A Barley Endosperm Bioassay for Gibberellins

Since the review of bioassay techniques for gibberellins by Phinney and West[1], several new techniques have been proposed[2–4]. These are based on the increased elongation of plant tissues induced by gibberellins. Recent work has defined other biological characteristics of gibberellic acid (GA_3), notably a stimulation of the hydrolytic enzymes in germinating cereal grains[5]. Paleg[6–8] demonstrated that this response resides in the cereal endosperm, and the bioassay reported here was developed from procedures used in those studies.

A naked barley variety, Triple Awned Lemma, was used to obviate dehusking the grain prior to sterilization. Seeds were soaked in a freshly prepared sterilizing solution of bleaching powder (4 per cent w/v) for 24 h and rinsed ten times in 100-ml. lots of distilled water. Seeds were then cut transversely 3 mm from the distal end with a razor blade and the embryo-containing fragment discarded. The remaining endosperm portions were weighed in groups of 4, each group being placed in a 2 in. × 1 in. specimen vial containing 1·0 ml. of the test solution. Each vial contained 0·05 ml. streptomycin (10 mg/ml.), either 0·5 ml. GA_3 solution or 0·7 ml. plant extract and water to a total of 1·0 ml. The stoppered vials were placed in an oven maintained at 30° C for 48 h and samples of the ambient media were then assayed for reducing sugars by the procedure previously described[6]. A typical dosage-response curve is shown in Fig. 1. In all experiments duplicate observations were made at each standard GA_3 concentration and triplicate observations on each plant extract.

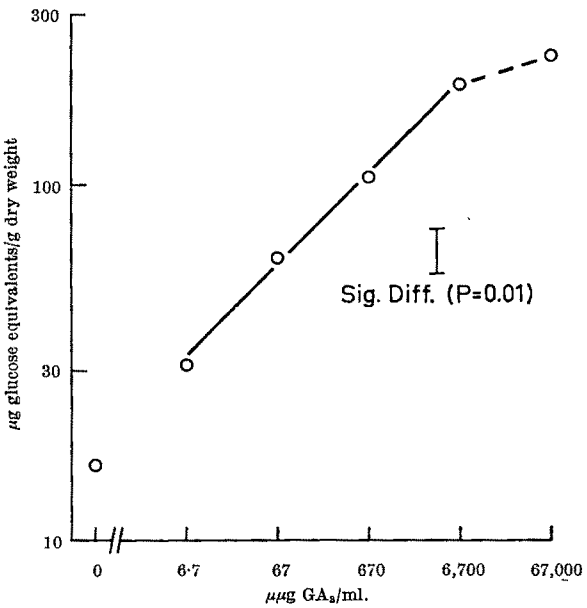

Fig. 1. Response curve of amounts of reducing sugars (glucose equivalents) released from barley endosperm treated with various doses of GA_3. The concentrations of the GA_3 solutions ranged from 2×10^{-11} M to 2×10^{-7} M. The curve represents the mean of three experiments

It has been found that 6·7 μμg (2×10^{-11} M) GA_3 gives a response which is generally significantly greater than water control and that the response at 67 μμg is invariably significant. In the dwarf pea and dwarf corn tests a significant response may be obtained from 1,000 μμg GA_3 applied to each of 10 plants, and Naylor and Simpson[4] have demonstrated a response to 250 μμg GA_3 in the bioassay based on germination of excised *Avena fatua* embryos. It is suggested that the smallest detectable amount in the barley endosperm bioassay is of the order of 10 μμg GA_3, a feature which enables the use of extracts of smaller quantities of plant material than has been examined hitherto[9]. For example, an ethyl acetate extract of 2 mg of freeze-dried barley inflorescences (3–4 inflorescences) was estimated, after evaporation and solution of the residue in water, to contain 2·4 μg gibberellic acid equivalents per gram dry weight. There was sufficient activity in this extract to obtain significant responses from 10- and 100-fold serial dilutions; the dosage-response curve was parallel to the standard.

Neither indolyl-3-acetic acid nor 6-furfuryl-aminopurine has been found to cause a response in the bioassay (in contrast to the recent report of Boothby and Wright[10]); but inhibitors of sulphydryl-containing enzymes do inhibit the sugar release. Gibberellins other than GA_3 also induce the release of reducing sugars from barley endosperm and hence the bioassay would appear to be a valid and sensitive bioassay for endogenous gibberellin-like substances.

One of us (P. B. N.) has held a C.S.I.R.O. senior postgraduate studentship during this work.

A Periclinal Chimæra in Tea

Since the production of new morphological types in the course of grafting experiments of tomato on *Solanum nigrum* in 1910 by Winkler[1] and the description of the difference between the white-edged and solid-green leaf varieties of *Pelargonium zonale* by Baur[2], the spontaneous occurrence of chimæras, particularly in fruits and flowers, has been reported in many crops and ornamental plants. More recently, Sativa and Blakeslee[3] have reported the induction of chimæras by treatment of germinating seed with colchicine. The occurrence of a chimæra in tea of the type described, however, has not been previously reported. Gadd[4], in a discussion of non-infectious chlorosis in tea, says: "The yellow colour is due to lack of chlorophyll, though why it should not develop normally in particular zones is not known".

Chimæras are plants having genotypically distinct tissues lying adjacent to one another. The periclinal chimæra, which is the most stable, has an entire layer of tissue, one, two or more cells in depth, surrounding a particular organ.

The periclinal chimæra of tea (*Thea sinensis*, L.) described was found at Mount Vernon Estate in the Dimbula (Patna) region of Ceylon at an elevation of 4,017 ft. The plant was 5 ft. high and was bifurcated at the base of the main stem. One of the two main branches and its laterals produced only normal, green-coloured leaves, while the other branch and its laterals had leaves with a white-edged margin (Fig. 1).

The laterals on the branch producing normal leaves were at an angle of 45° from its main axis, while the laterals on the branch with white-edged leaves were at an angle of 60° from its main axis, the latter giving the

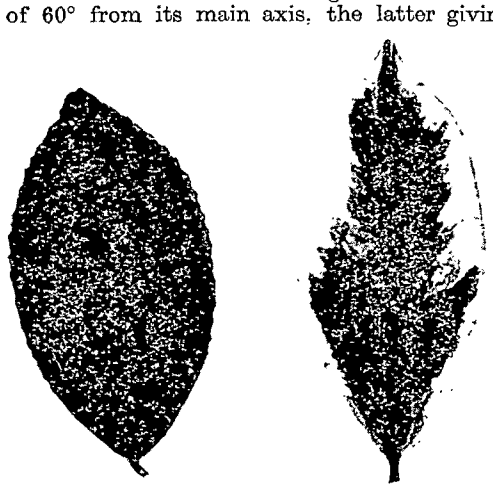

Fig. 1. Left, normal leaf; right, periclinal chimæra

appearance of a 'witches broom'. Cuttings propagated from the normal branch produced normal leaves only and cuttings propagated from the aberrant branch produced leaves with a white-edged margin only. This difference could be explained on the basis of a mutation in the bud primordium in the somatic tissue which produced the branch bearing leaves with a white-edged margin. Since the mutated, tissue surrounds the normal tissue, it is a periclinal chimæra.

Maximum of Starch during Spring in the Woody Plants (*Vitis riparia* Michx.)

Investigation of carbohydrate metabolism, carried out with lignified grape-vine[1], proved the sugar⇌starch interconversion to be characteristic for this plant as in other woody plants[2]. The changes in the vines, both those which spend the winter on the rootstock, and the others cut off and stored in the pit, can be characterized by a sugar→starch conversion in the late summer, by a starch→sugar in autumn, respectively, early in the winter, and at the beginning of spring once more by a sugar→starch conversion[3].

It is the changes in the carbohydrate during the early spring period which interest us here.

In the course of our experiments the grape-vine (*R. portalis*) was brought, at the time of the sugar-maximum, in two different pits to a temperature of about +8°–10° C and +25°–30° C, respectively. The content of carbohydrate was determined monthly by means of anthron-reagent[4].

The beginning and the course of the synthesis of starch, just as the values of the starch-maximum, are dependent on the temperature. At a temperature of about +8°–10° C there is no decrease in the total values of the carbohydrates, until the development of the starch-maximum. This very fact indicates little respiration. It is remarkable how rapidly the decrease of the total carbohydrate—as a result of an intensified respiration[5]—begins immediately after the starch-maximum.

At +25°–30° C the carbohydrate reserve disappears quickly, and at the same time new organs are formed through the energy set free by it—callus-tissues, shoots and roots.

The obligate connexion of the respiratory oxidation with the phosphorylation is a well-known phenomenon[6].

$$\left.\begin{matrix} DPNH_2 + 1/2\ O_2 \\ +3\ ADP + 3\ P \end{matrix}\right\} \rightarrow \left\{\begin{matrix} DPN + H_2O \\ +3\ ATP + 3\ H_2O \end{matrix}\right. \quad (1)$$

It appears that the intensity of respiration is determined by the intracellular ADP : ATP quotient[7], and indirectly by the biosyntheses promoting ATP[8]. The intracellular localization of ADP and that of ATP must also be taken into account, since the diffusion through the membranes of the mitochondria is an easy matter for ADP, whereas ATP permeates it in a limited way, though it can be rapidly used by the different organs of the cell[9].

The changes of carbohydrate are the result of the amylophosphorylase, acting in both directions[10]:

$$\text{glucose-1-phosphate} \rightleftharpoons \text{starch} + PO_4^{3-} \quad (2)$$

The synthesis of starch begins with the phosphorylation of either glucose or fructose:

$$\text{Glucose (fructose)} + ATP \xrightarrow[\text{hexokinase}]{} \text{glucose (fructose)-6-P} + ADP \quad (3)$$

Hexokinase therefore requires ATP for the synthesis of starch. This enzyme is one of the most important precursors of the 'glycolysis'. The sudden beginning and the subsequent stagnation of the carbohydrate utilizing respiration (Fig. 1*a*), must be assigned to the change of the phosphate acceptor-concentration. On this spot ADP acts as a feedback mechanism[6]. The most probable explanation for this phenomenon lies in the supposition of Hess and Chance[9]. Accordingly, the hexokinase uses the ATP-quantities present in the cytoplasm:

$$ATP \rightarrow ADP + PO_4^{3-} \quad (4)$$

ADP permeates, as an acceptor for the oxidizing phosphorylation, from the cytoplasm into the mitochondria, inducing there the 'endogenous respiration'. At a low temperature, this process will take a time as long as the ADP—quantities of the mitochondria, for their greatest part, become phosphorylated into ATP. The respiration must then stop, because—as contrasted with Fig. 1*b*—there is no on-going process of organization utilizing energy. The permeation of the intramitochondrial ATP into the cytoplasm is, in fact, highly limited and the syntheses bound to the mitochondria are still inhibited at this low temperature. As a consequence of deficiency in ATP-quantities by the cytoplasm, the activity of the hexokinase (3), and thereby the amylophosphorylation (2) is limited. In case the syntheses are not inhibited by low temperature (Fig. 1*b*), the starch-maximum becomes lower and the spontaneous regulation of the respiration blends.

By reason of the considerations put forward in this communication, we continue to uphold our earlier hypothesis, according to which the starch may serve as a direct substrate for the respiration[3]. In this way the synthesis of starch before the sprouting is energetically established, because, under these conditions, the release of the glycolytic phase of the respiration from the 'pre-

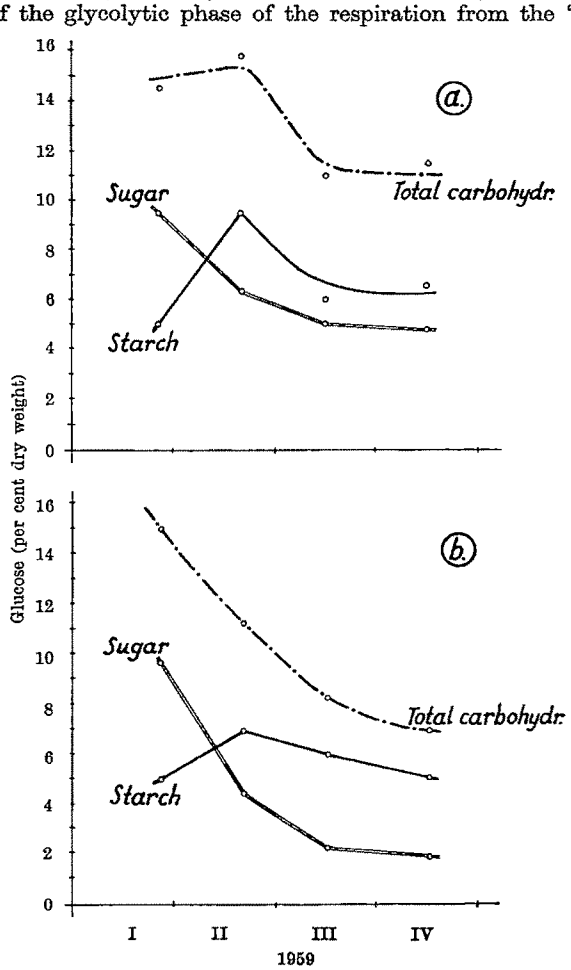

Fig. 1. Changes in the carbohydrate content of the lignified vines stored at different temperatures. Storage temperatures: *a*, 8°–10° C; *b*, 25°–30° C

cursory' control of the ATP-requiring hexokinase is just possible. The high ADP- and PO_4-concentration, at the same time, will ensure the possibilities of a quick oxidation for the substrates of respiration. The respiratory energy-production—the oxidizing phosphorylation—thus has a free path for the intensive biosyntheses related to sprouting.

Heat-death Temperature in *Allolobophora terrestris* (Sav.) forma *longa* (Ude) and *Eisenia foetida* (Sav.)

An endeavour to deparasitize earthworms by heat in order to obtain infection-free hosts (for experimental purposes described elsewhere[1,2]) revealed an interesting difference of probable ecological significance between the two species *Eisenia foetida* (Sav.) and *Allolobophora terrestris* (Sav.) forma *longa* (Ude) (henceforth referred to here as *Allolobophora longa*).

The method of deparasitization by heat was used by Macdougall[3] to kill the gregarine parasites in the larvæ of *Tenebrio* sp. To make use of this method with earthworms it was first necessary to determine the heat-death temperature of the worms under specific conditions. Smith[4], using crude methods, observed that temperatures of 35°–40° C were fatal to *Allolobophora foetida* Sav. (= *Eisenia foetida* (Sav.)) but she did not specify the duration of exposure nor the pre-condition of the worms. Wolf[5,6], using very small numbers of specimens (six per trial), determined the heat-death temperature for *Lumbricus terrestris* (L.) as 28° C for an exposure of 400 min. In the experiments described here it was decided to determine the highest temperature which worms could survive after 12 h exposure (as long exposures were more likely to be effective in deparasitizing worms). The criterion of survival adopted was 80 per cent survival in soil at room temperature, 48 h after the end of an exposure of 12 h to the temperature under review. All worms used in the experiments were adult, and had been acclimatized in the same soil at a mean laboratory temperature of 15° C for a period of at least four weeks.

Worms were exposed to the differing temperatures by floating them individually in boiling tubes in thermostatically controlled water baths. Each tube was ballasted with clean moist gravel to make it float with the lip of the tube an inch above the water surface. Under these conditions the interior of a tube, at the surface of the gravel, attained the same temperature as the water bath in less than ten minutes after immersion. Worms were subjected to a particular temperature in batches of 20. They were taken from well-fed laboratory cultures, and washed in water at laboratory temperature before being placed in the boiling tubes floating in the water bath. 12 h later the worms were removed and placed individually in soil in lidded glass dishes and then examined after a further 48 h. Batches of 20 control worms were floated under similar conditions in water at room temperature.

In order to incorporate a confirmation procedure into the experiments (and also to shorten the total time taken) observations were made with two separate water baths—one to begin with a temperature near the lower limit for heat-death given by Wolf[6] and the other to begin with a temperature near the upper limit given by Smith[4]. Thus one bath was maintained at 20° C while the other was at 38° C for the first trial. Specimens of both species were placed in each bath. Successive approximations were then made, using fresh batches of worms for each water bath for each trial, making the 'cool' bath hotter and the 'hot' bath cooler. After the second trial the difference between the species had become sufficiently obvious to enable them to be segregated, *E. foetida* into the 'hot' bath and *A. longa* into the 'cool' bath. Trials were continued until the criterion of survival was satisfied in each case.

In the case of *E. foetida* the critical temperature was 33·3° C; in the case of *A. longa* it was 25·7° C. This very marked difference in heat-death temperature not only points to a difference in the powers of physiological adaptation of the two species but would also explain the ability of *E. foetida* to survive the relatively high temperatures in compost heaps. It may also be associated with the habit of æstivation in the deeper soil layers, seen in *A. longa* in spells of hot dry weather.

ENTOMOLOGY

Effect of Low Temperature on the Induction of Imaginal Differentiation of Dauer Pupa of the Silkworm

In lepidopterous insects (in which diapause occurs in the pupal stage), the pupal brain is activated by treatment by low temperature[1–5]. It has not yet been established, however, whether artificially diapausing, brainless pupæ (dauer pupæ) are activated by low temperature. Therefore, this question has been investigated by chilling dauer pupæ of the silkworm, *Bombyx mori*.

Bombyx pupæ of F_1 hybrids between two strains, *J*.122 and *C*.115, from the Sericultural Experiment Station, Tokyo, were used as specimens. The brain was extirpated from each individual immediately following pupation[6], and the brainless pupæ were kept for 56 days at 25° C following ablation.

Three groups of dauer pupæ, 56 days old, were maintained for 20, 40, and 60 days at 5° C respectively. Afterward, animals in each group were kept for 30 days at 25° C. The control consisted of non-chilled dauer pupæ at the same age already mentioned which were observable for 46 days at 25° C following operation.

Moths did not appear in group 1 for 30 days after chilling (Table 1). However, two out of twenty-five dauer pupæ in both group 2 and 3 emerged as moths in 23–26 days following treatment, but no other animals emerged for 30 days. Moreover, of twenty-five dauer pupæ used as controls, four animals emerged as moths respectively on days 132 (♂), 138 (♀), 138 (♂), and 146 (♀) following removal of their brains. Other animals did not show any sign of imaginal differentiation for 146 days.

After treatment with either oxygen or carbon monoxide, more than half of the dauer pupæ tested emerged as moths in 30 days following treatments[7]. Also, when a fresh brain was implanted into each dauer pupa, the implanted animal became a moth in 18–25 days following implantation[8]. On the contrary, the effect of low temperature on induction of imaginal differentiation of each dauer pupa is very weak, if present at all, as demonstrated in Table 1. Moreover, as suggested in Kobayashi,

Table 1. Effect of Chilling on Imaginal Differentiation of Dauer Pupæ

Groups of exp.	Duration of chilling (days)	No. of specimens	No. of moths emerged* (days to emergence following chilling)	No. of undeveloped pupæ
1	20	25		25
2	40	25	1 (23), 1 (36)	23
3	60	25	2 (23)	23

* During 30 days at 25° C (following chilling).

Fukaya and Mitsuhashi's work[9], most dauer pupæ emerged as moths in 120–300 days following extirpation of brains under the same conditions.

Because of the reasons mentioned here, and the results presented, it is not likely that low temperature affects the induction of imaginal differentiation of dauer pupæ, that is, the prothoracic glands in dauer pupæ are not usually activated by treatment with low temperature, although a few animals did emerge as moths.

We thank Mr. Koji Nomura, of the Laboratory of Clinical Biology, Salt Lake City, for assistance during the course of this experiment, and Mr. Y. Ishitoya and Miss K. Tani, of the Sericultural Experiment Station, Tokyo, for help with the rearing of the silkworms.

Feulgen – Schiff's Technique for Examination of the Distribution of the Intracellular *Rickettsia*-like Micro-organisms in Whole Mounts of Ticks, or their Tissues

Intracellular *Rickettsia*-like micro-organisms are known to exist naturally in ticks, usually occurring in the Malpighian tubules and oocytes[1,2]. Their distribution in the organs of the ticks has been, in the past, studied by various investigators[3,4] from conventionally stained smears and sections of tick tissues.

Histochemical methods for nucleic acids, including the Feulgen technique, have recently been used in this laboratory with sectioned material of ticks[5,6] to demonstrate in virtue of the persisting DNA content of the micro-organisms, their occurrence and distribution in the tick tissues. This type of work, however, entails dissection and serial sectioning of a considerable number of ticks.

Recently, Newcomer[7] has introduced for serial-section studies a histochemical technique, in which tissues are fixed in isopropanol fixative[8], then treated with Feulgen–Schiff's reagent before embedding. However, by modifying Newcomer's technique, I was able to overcome this tedious matter of surveying ticks in serial section and to observe directly in whole dissected ticks under the binocular microscope the occurrence and distribution of the intracellular *Rickettsia*-like micro-organisms which are to be found in their Malpighian tubules and developing oocytes. The modified technique, depending on selective straining of the DNA of the micro-organisms, is as follows.

Ticks are dissected in 0·9 per cent saline. The dorsal integument is gently separated from underlying tissues, and the alimentary canal removed. The organs thus exposed are then covered *in situ* with the fixative, isopropanol mixture, and kept thus for 1–2 days. Hydrolysis of the dissected ticks follows in N hydrochloric acid at 60° C for 10–20 min. The ticks are then treated with Schiff's solution, prepared according to the method of Newcomer[7], for 20–30 min, and washed in sulphurous solution several times. After washing in running water, they are passed through graded alcohols up to 70 per cent. The treated ticks can then be fixed in a dissecting dish and examined in 70 per cent alcohol for the micro-organisms under the binocular microscope. Moreover, pieces of Malpighian tubules and oocytes could also be removed at this stage from the ticks, dehydrated, cleared in xylene and mounted for microscopic examination in D.P.X.

As would be expected with a DNA-selective stain, tissue nuclei persisted and were stained, in this technique, purplish-red. In addition the DNA-positive *Rickettsia*-like micro-organisms were also seen in the cytoplasm of Malpighian tubule cells and of oocytes as purplish-red aggregates. Their distribution was readily determined, and confirmed by microscopic examination of mounted pieces of those tissues.

Several species of argasid and ixodid ticks have been investigated in this way, and different patterns of distribution of the micro-organisms observed particularly in the Malpighian tubules. The results of these investigations using this and other techniques are in preparation for publication.

I thank Prof. D. S. Bertram, director of this Department, for his interest.

MICROBIOLOGY

Host-range of *Proteus morganii* Bacteriophages

Colicine *H*, which kills many *Escherichia, Shigella, Salmonella* and a few *Proteus hauseri*[1] also attacks many strains of *P. morganii*[2]. The relationship between *P. morganii* and the other genera mentioned has recently been strengthened by the finding[3] that the guanidine + cytosine content of their deoxyribonucleic acids are very similar and differ from *P. hauseri, P. rettgeri* and *Providence* strains. On the other hand, it has been shown[4,5] that although *P. morganii* strains are not susceptible to *P. rettgeri* phages, many *P. morganii* organisms are attacked by *P. hauseri* and *Providence* phages. There is also a well-known antigenic relationship between *Proteus morganii* and *P. hauseri*. Work on *P. morganii* phages has been confined to temperate varieties, and host-range determinations were limited to the *Proteus* group of organisms[2,6]. The phages were found to be species specific. In view of the uncertainty[7] about the taxonomic position of *Proteus morganii*, it was decided to investigate the action of *P. morganii* phages derived from both lysogenic strains and sewage on members of the family Enterobacteriaceae.

The 17 strains of *Proteus morganii*, 28 strains of *P. hauseri*, 22 strains of *P. rettgeri* and the 24 *Providence* strains used have been described[5]. The other Enterobacteriaceae comprised 21 *Salmonella* serological varieties,

30 isolates of *Escherichia coli*, 4 serological varieties of *Shigella flexneri*, 3 varieties of *Sh. boydii*, 2 strains of *Sh. schmitzii*, 4 of *Sh. sonnei* and 30 strains of *Serratia marcescens*, of which 15 were from the National Collection of Type Cultures. Media and techniques were as previously described[4,5].

Phage was isolated from sewage against 16 of the 17 strains of *P. morganii*. In many instances a lysate produced more than one kind of plaque but further work was confined to one phage/organism. All 17 strains of *P. morganii* proved lysogenic by ultra-violet induction for one or more of the *P. morganii* or other strains tested. Because of the complete success of the ultra-violet method of induction no other methods were used to demonstrate lysogeny. All phages could be differentiated by their host-ranges.

Eight strains of *P. rettgeri* were lysed by 1 or more of 10 of the sewage phages, and 9 of the *Providence* cultures were attacked by 1 or more of 3 sewage and 4 temperate phages. Twenty-one of the *P. hauseri* strains were lysed by 1 or more of all 17 sewage and 6 of the phages derived from lysogenic strains. None of the 33 phages had any action on the *Salmonella* strains and only 1 temperate and 1 sewage phage productively lysed single strains each of *S. marcescens*. On the other hand, 10 strains of *E. coli* and single strains of *Sh. sonnei* and *Sh. boydii* were susceptible to one or more of 5 temperate and 14 of the phages derived from sewage. The efficiency of plating of all the phages on heterologous hosts approached unity and no abortive infections were noted.

Isolated instances of common antigens present in *Escherichia*, *Shigella* and *P. morganii* have been described[3], but these groups of organisms certainly do not possess the degree of susceptibility to individual phages which they exhibit to colicine *H*.

The *Proteus* group of organisms are regarded as less closely related to *Escherichia*, *Shigella* and *Salmonella* than the latter are related to each other[2]. The work recorded here has shown that *P. morganii* phages possess a degree of extra-genus activity far greater than other *Proteus phages*[4,6] and this may support (along with other evidence mentioned) an intermediate position for *P. morganii* linking the genera *Escherichia* and *Shigella* to the *Proteus* group of organisms.

This work was supported by the South African Council for Scientific and Industrial Research.

Overnight Incubation Technique for obtaining Transformable *Bacillus subtilis* Cells of Reproducible Competency

The use of *Bacillus subtilis* for DNA-mediated transformation investigations has found wide acceptance since the system was described by Spizizen[1] in 1958. In all bacterial transforming systems, technical difficulties arise in having available at the desired time a recipient bacterial population containing a high per cent of transformable (competent) cells. The usual preparation of *B. subtilis* recipient cells involves overnight incubation in broth, a 4-h period in growth medium followed by a 90-min period in transformation medium before maximum competence is obtained[2]. These freshly prepared cells are highly competent, although the competence-level will vary and cannot always be predicted.

In order to obtain reproducible results and to shorten the preparatory procedures for obtaining competent cultures, many investigators have utilized frozen cells. *B. subtilis* cells are rapidly frozen in a glycerol-containing medium either just before or just after the 90-min period in transformation medium. Cells frozen before the attainment of competence may be stored at $-20°$ C (ref. 3) while the already competent cells are stored at temperatures below $-40°$ C (ref. 4). In my experience, any slight deviation above $-40°$ C in the latter case resulted in a drastic loss of competency. In neither case was it possible to predict the competency from day to day over a long period of time. Recently a technique has been reported for freezing replicate competent cultures in liquid nitrogen and storing them at a temperature of $-196°$ C (ref. 5). Although cultures prepared by this method may give more precisely reproducible transformation frequencies, the practical advantages of the present procedure would seem to make it ideal for most experimental purposes.

The routine method reported here for obtaining transformable *B. subtilis* cultures produces cells the competency of which can be closely predicted over a long period of time, uses a convenient overnight incubation technique and has the added practical advantage that the frozen cell inoculum may be stored at $-20°$ C. A satisfactory uniform inoculum is obtained by the use of cells which have been propagated on synthetic growth medium for 4 h prior to freezing. These cells can be used for several months. For daily work a culture is incubated overnight at 30° C in synthetic growth medium rather than the usual 4-h period at 37° C. Cells usually develop the maximum potential for competence during the latter part of the logarithmic growth phase[2]. For overnight culture, the growth rate is further decreased by using a small inoculum and less vigorous aeration. Under these conditions, the maximum potential for competence is attained at 16 h and does not decrease until about 18 h.

B. subtilis strain *SB*-19 was used as the DNA donor and the indole-requiring strain 168 as the recipient. The synthetic growth medium and transformation medium utilized have been described[2]. A temperature-controlled water bath-reciprocal shaker (Research Specialties, Richmond, Calif.), stroke length 1·5 in., was used for aeration. Erlenmeyer flasks of 125-ml. capacity containing 20 ml. of medium were used for growing all cultures. Transformation was conducted in 18 mm × 150 mm culture tubes, with metal caps, containing a total volume of 1 ml. Transformant colonies, with no interfering background growth, were easily counted after overnight incubation on the following medium. Spizizen's minimal medium[2], solidified with Oxoid 'Ionagar No. 2' (1 per cent) or Difco 'Noble Agar' (1·3 per cent) was autoclaved at 15 lb. pressure for a time sufficient to cause the agar to become slightly amber. Glucose was added aseptically after autoclaving as also was vitamin-free casein hydrolysate-acid (Nutritional Biochemical Corp.) to a concentration of 0·02 per cent. With less autoclaving time, the agar was white and only pinpoint-sized transformant colonies developed after overnight incubation. Colonies on amber agar were much larger, but colony count was not affected. The nature of the growth-promoting response has not been investigated. Total viable counts were performed on the same medium supplemented with *l*-tryptophan, 5 μg per ml.

For preparation of the cells for freezing, strain 168 was grown overnight in 'Penassay Broth' (Bacto Antibiotic Medium 3) with vigorous aeration at 37° C. At the end of 16 h there were $3–5 \times 10^8$ colony formers per ml. The broth-grown cells were sedimented, washed once with growth medium and carefully resuspended in 10 volumes of growth medium to give a homogeneous suspension. The flasks were incubated with slow shaking, 50 c.p.m., for 4 h at 37° C. After centrifugation, the cells were resuspended in 0·75–1 volume of Spizizen minimal medium[2] containing 5 per cent glycerol and dispensed, 1 ml. per screw cap tube.

Table 1. Reproducibility of Results obtained with Frozen Cell Inoculum and Overnight Incubation in Growth Medium at 30° C

Exp.*	Transformants/ml.† ($\times 10^4$)	Total colony formers/ml. ($\times 10^8$)	Transforming activity (%)
1	2·8	2·2	0·013
2	2·3	2·2	0·011
3	2·6	2·5	0·010
4	2·7	2·3	0·012

* Experiments performed on different days over a period of two weeks.
† Used 0·02 μg DNA/ml. in transformation tube.

After standing about 20 min, the cells were quickly frozen in a dry ice–ethanol mixture and stored at −20° C. The final cell concentration was $1{\cdot}5–2 \times 10^8$ per ml. If greater aeration was provided during the 4-h growth period by increasing the shaker speed or altering the volume to surface ratio, the cultures were not as satisfactory for subsequent preparation of competent cells.

The transformation procedure finally adopted for daily use with the frozen cell inoculum is as follows: All incubations are carried out at 30° C. The cells are thawed, diluted to give $2–4 \times 10^7$ cells per ml., and 0·1 ml. is inoculated into 20 ml. of growth medium. The flask is incubated overnight with shaking, about 100 c.p.m. At 16–18 h, the cells are sedimented and resuspended carefully in transformation medium to give usually a 1 : 3 or 1 : 5 dilution The best dilution to use must be determined with each new batch of frozen cells. After dispensing 0·9 ml. per tube, the cultures are shaken at 125 c.p.m. (not critical) for the usual 90 min (ref. 2). After a 30-min contact with DNA and a 10-min reaction with deoxyribonuclease, the cells are ready to be diluted and plated.

From the results given in Table 1, it can be seen that consistent and predictable results are obtained from day to day. The number of viable centres in the transformation tube and the fraction which becomes competent remain quite constant. With different lots of frozen cells, the transformation efficiency with limiting concentrations of DNA (0·02 μg per ml.) varied from 0·01 to 0·07 per cent. Since about 2×10^8 cells/ml. were present in the transformation tubes, this frequency was very satisfactory for quantitative assays of transforming activity. Freshly prepared competent cells transform frequently at an efficiency of 1–2 per cent with saturating concentrations of DNA[2].

Several batches of frozen cells have been prepared and all have given satisfactory results over a period of several months. Since the procedure was developed empirically, the optimum conditions for transformation efficiency probably have not been achieved. It has been noted, however, that neither 27° C nor 37° C were satisfactory for overnight incubation in growth medium. At 30° C, raising the shaker speed from 100 to 120 c.p.m. or increasing the inoculum 2–3 fold caused the peak for maximum potential for competence to occur at 12 h, which was not suitable for overnight incubation. Varying the time in transformation medium gave no added advantage.

Saito *et al.*[6] reported overnight growth of a *B. subtilis* heat-shocked spore suspension at 27° C and subsequent transformation by a 2-h contact with 30 μg/ml. of DNA at 37° C. The long contact with DNA was necessary for greatest transformation efficiency. In the procedure reported here, both growth and transformation incubations were done at one temperature (30° C) and a 30-min contact with limiting concentrations of DNA gave high yields of transformants.

VETERINARY SCIENCE

Formation of Histamine in Ruminal Fluid

Histidine and other amino-acids normally undergo deamination in ruminal fluid[1], and decarboxylation with the formation of histamine does not normally occur in the rumen to any great extent. When sheep or cattle are fed a diet containing excessive amounts of carbohydrate, however, the histamine content of ruminal fluid may increase considerably and concentrations >70 μg/ml. have been recorded[2]. Van der Horst[3] has shown that the concentration of amino-acids and amines in ruminal fluid can be increased by incubation with glucose.

In the investigation recorded here ruminal contents have been incubated with glucose under a variety of conditions and the concentrations of histamine formed have been assayed biologically on the guinea pig ileum preparation. Fluid was obtained from half-bred ewes fitted with permanent ruminal cannulæ. Glucose (20 mg/ml.) was added and samples were incubated for periods of 3, 18, 24, 48 or 72 h. In some experiments 1·5 mg/ml. L-histidine was also added. Histamine concentrations were compared with those obtained from identical samples containing boiled ruminal fluid. (The histamine concentration of the latter never exceeded 0·1 μg/ml.)

Results for 2 such experiments with fluid from the same sheep are shown in Fig. 1. Incubation for periods of more than 3 h caused a fall in *p*H, which thereafter remained at 4·0–4·5. Samples incubated for less than 24 h produced little histamine. The concentration of histamine did not increase much after 24 h, but in one experiment there was a further rise during the period 48–72 h. Incubation of samples from other sheep gave similar results.

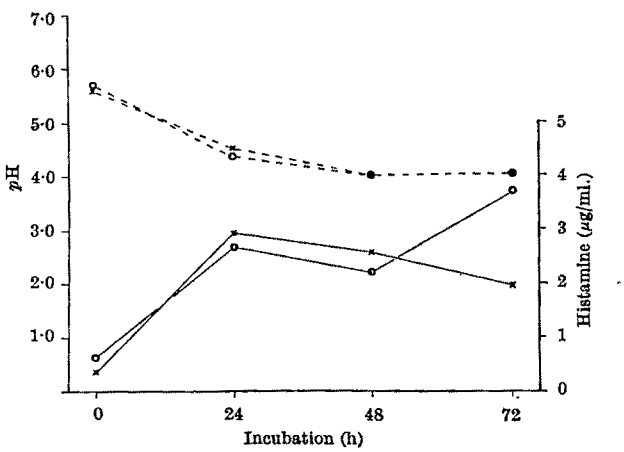

Fig. 1. Histamine formation and changes in *p*H of ruminal fluid incubated at 37° C with 2 per cent glucose. – – –, *p*H; ——, histamine content; O, Exp. 1; ×, Exp. 2

Histamine formation was not greatly increased by the addition of L-histidine to give a concentration of 1·5 mg/ml. Pyridoxal 5-phosphate, reported to be a co-enzyme of tissue histidine decarboxylase[4], was added to some samples without effect.

Excessive carbohydrate intake was attained experimentally by dosing sheep with glucose[5]. Sheep, fitted with permanent ruminal cannulæ, were given 3 successive doses of 300 g glucose dissolved in 500 ml. water in 6 h. Samples of fluid were removed at intervals during the following 5 days for determination of *p*H and histamine content. Results obtained with 3 sheep are shown in Fig. 2.

Acidity increased rapidly in the first 6 h and the *p*H had fallen to 4·0–4·5 at 24 h. After 24 h the *p*H returned slowly to normal in two sheep but remained low in the third sheep for a further 24 h. The histamine content of ruminal fluid showed some increase at 24 h, but there was a secondary peak at 48–52 h in all three sheep. In two

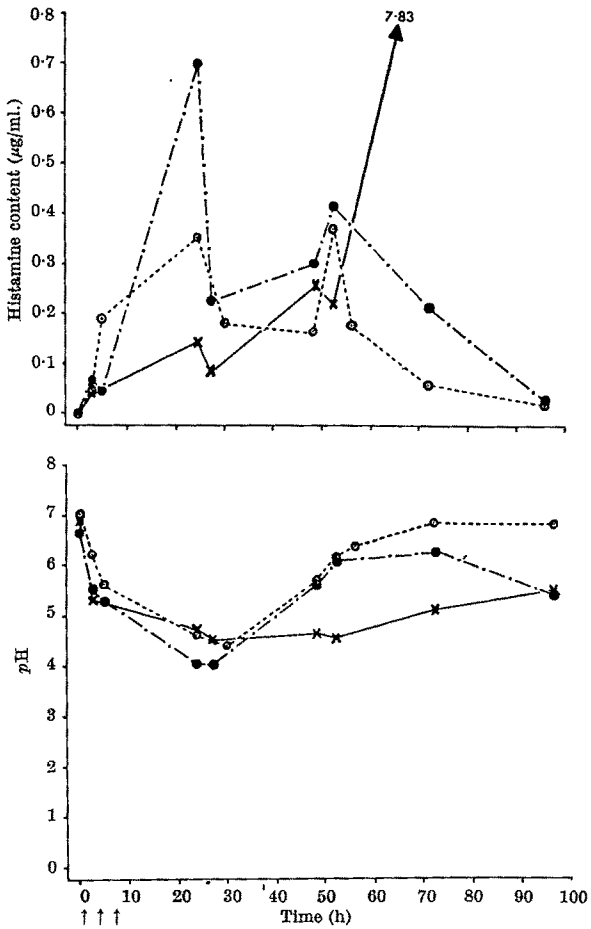

Fig. 2. The effect of *p*H and histamine content of adding glucose to ruminal contents of three cannulated sheep. ×, S_5; ●, S_8; ○, S_{16}; ↑, 300 g glucose

sheep the histamine content fell afterwards to reach normal limits by 96 h. In one sheep (*S5*), however, in which the *p*H of the ruminal contents remained low, histamine concentration increased to 7·8 μg/ml. at 72 h and was > 3·0 μg/ml. at 96 h.

In all three sheep, the increase in histamine content appeared to depend on a fall in *p*H and where high acidity persisted a marked increase in histamine content occurred. The delay of 24 h between the fall in *p*H and the rise in histamine content suggests that histamine formation might result from a change in ruminal flora brought about by the altered environment. This view is supported by the similar delay in incubation experiments and by the finding that incubation of normal ruminal fluid with histidine for periods of 3–4 h with or without the addition of glucose did not result in histamine formation.

Further investigations are in progress to obtain a more quantitative assessment of the rate of histamine formation in the rumen and to measure the histidine-decarboxylating activity of ruminal samples withdrawn at different stages in the experiment.

I thank Imperial Chemical Industries, Ltd., for a grant towards this investigation.

GENETICS

Study of Several Gene Frequencies in Yugoslav Population

Recent years have witnessed a rather rapid development of the population genetics of certain hereditary characters in man. Its findings are based mostly on the analyses of material obtained from voluntary blood donors[1–3]. This method of collecting research material has numerous advantages, but also several marked disadvantages. For example, data on the frequency of hereditary characters are mostly limited to the antigen properties of red blood cells[2]. The value of work in population genetics increases with the number of analysed genes from a certain population sample. Some of the genes being factors of marked polymorphism in man, their frequency can lead us to remote ancestors, and genes can serve as markers in the study of linkage in the chromosomes in man, where the need for just such markers is felt most acutely[4].

For these reasons we have tested a group of healthy young persons in order to discover normal hereditary characters. Some of the tests used are rarely performed in the blood transfusion services.

The blood groups of ABO, MN, Rh(D) systems, saliva secretion status, PTC threshold, and serum haptoglobin (Hp) types of 459 medical students (male 198, female 195) between eighteen and twenty-two years were determined. In this way a total of 14 genes was registered for every person tested. Each person first gave several ml. of saliva, was then tested with PTC and finally gave several ml. of venous blood. The test lasted six days and took place in the beginning of May 1962.

Blood groups and factors were determined by standard methods[3], with the application of absorbed anti-A_1 serum and specially prepared extract of seeds of *Ulex europaeus* to detect a possible 'Bombay' type[5–7]. The secretion status, namely, specific groups of substances in saliva, were determined by McConnell's method[8] with the application of the *Ulex europaeus* (anti-H,O) extract. The method used in determining taste sensitivity for bitterness was that of Harris and Kalmus[9]. Three common Hp-types from serum were determined by our modification of Smithies's method of vertical electrophoresis in starch gel[10,11].

The results obtained are shown in Table 1. A statistical elaboration of results shows that the sample is representative of the tested population, because with corresponding degrees of freedom χ^2 values indicate a high

Table 1. Phenotype- and Gene-frequencies of Tested Traits among 459 Students

probability. No tested character shows any difference in values between males and females.

As for the ABO system frequency, our results are very similar to those already published[12,13] for the territory of Yugoslavia. The same holds good for MN and Rh(D) factors, except that the frequencies of Rh negative phenotypes are somewhat lower[13] in our material. According to the published[11,14] and unpublished observations of the distribution of Hp-types in Yugoslavia, the results shown match those from certain areas, bearing in mind the fact that the Hp^1 frequency of our sample is slightly lower than the average frequency found in Yugoslavia until now. We have no data concerning the ABH secretion status of our healthy population[15], but a comparison with some sources[3] shows that the frequency of non-secretors in our sample is lower than the European average (about 23 per cent). The frequency of non-tasters in this test corroborates the existing data[16,17] regarding the distribution of this hereditary character in our populations. Laboratory analyses did not yield a single 'Bombay' type. Generally speaking, frequencies of all tested characters agree with the distribution of the same characters in European populations[2,3,18–20].

This work reports an effort to answer the first of basic questions of human population genetics, propounded so brilliantly by Penrose[21]. We shall attempt to answer other questions in our further work.

Transferrin Variants in Finland

THE gene responsible for transferrin *C* seems to be very common in all human populations. Of the rare alleles, those producing the faster-moving variants have mainly been found in Caucasoids. The most common of them is B_2, which has been observed in 1 per cent of Canadian Whites, Englishmen and Swedes[1–3]. *Tf* B_1 has been reported in 1 of 139 British Whites[2] and 2 of 1,173 Swedes[3].

The more slowly migrating transferrins (*D* type) are rare in the white populations studied so far, but common in some other races. The phenotype CD_1 is found in about 10 per cent of the New York Negroes and Australian Aborigines[4]. In a Chinese population about 6 per cent of individuals were of the phenotype CD_{Chl}[5]. Reports on the occurrence of the *D*-alleles in Whites have been published by Harris *et al.*[6], who found 2 cases of CD_4 (CD_{0-1}) among 1,000 English and Italian samples; and by Beckman *et al.*, who discovered 6 CD_1 phenotypes among 329 Swedish Lapps[7] and 2 CD_1 phenotypes in 1,173 Swedes[3].

The sera of 354 unrelated Finns were examined by unidimensional starch-gel electrophoresis, using the discontinuous buffer system described by Beckman and Holmgren[7]. The electrophoresis was applied at 6° C with 10–12 V/cm for about 3 h. One drop of bromphenol blue in the gel buffer solution was added to the filter-paper slice soaked with the test serum, so as to make the albumin band visible during the migration. This did not interfere with the staining of proteins with amido black.

The distribution of different phenotypes in the series was: *CC* 338; B_1C 9; B_2C 1; CD_1 6.

None of the CD_1 individuals was born in Lapland, nor did they have parents born in Lapland. It seems that the frequency of the B_1 and D_1 genes in the Finnish population is remarkably high. Six of the families, in which the heterozygotes were found, were investigated more thoroughly. Twelve of their children had the parent's heterozygous phenotype, while nine were of the type *CC*. The pedigrees will be published later.

We wish to thank Dr. L. Beckman for supplying us with *Tf* B_1C, B_2C and CD_1 reference sera.

VIROLOGY

Antigenic Activity of Tryptic Peptides of Tobacco Mosaic Virus Protein

FRAGMENTS possessing immunological activity related to that of the whole protein have been obtained from several protein antigens. Enzymatic digests of silk fibroin[1], γ-globulin[2,3], and serum albumin[4,5] have exhibited such activity. A recent report from our laboratory showed that fragments of egg albumin obtained by partial acid hydrolysis of the protein inhibited both the *in vitro* interaction of the protein with homologous anti-serum and systemic anaphylaxis in guinea pigs[6]. Although active fragments have been obtained, analysis of their composition and structure is extremely difficult.

Proteins of known amino-acid sequence afford promising tools for studying antigenic determinants. Recently, Brown[7] reported on the antigenic determinants of ribonuclease. We present here our findings on the immunological activity of tryptic peptides of tobacco mosaic virus protein (TMVP), another protein of known amino-acid sequence[8,9].

The TMVP was obtained from the whole virus by treatment with 66 per cent acetic acid[10]. The protein was digested with trypsin for 2 h at 40° C maintained at *p*H 8·0 by a *p*H stat. The digest was passed through a '*G*50 Sephadex' column equilibrated and developed with M/300 phosphate buffer *p*H 8·0. Two fractions were obtained: $G_{50}S_1$ and $G_{50}S_2$, containing materials of molecular weight ranging above and below 10,000 respectively. The peptides contained in the $G_{50}S_2$ fraction were characterized by ion exchange chromatography[11,12] on a 'Dowex 1 × 2' column developed with a polygradient buffer system ranging from a collidine : pyridine buffer of *p*H 8·8 to 50 per cent acetic acid. They were also characterized by electrochromatography using the peptide mapping technique of Woody and Knight[13]. $G_{50}S_2$ contained the peptides characteristic of the tryptic digest of TMVP[12,13].

Anti-lysozyme + 220 μg D_2	Lysozyme 100	+

* Containing 60 μg antibody per ml.
† 220 μg of D_1 or D_2 are equivalent to 500 μg of $G_{50}S_2$.
‡ Antiserum diluted 1 : 50; intradermal injection of 0·1 ml. of anti-lysozyme serum diluted 1/50 and intravenous challenge with 100 μg lysozyme elicited a similar degree of dye infiltration to that elicited by the intradermal injection of 0·1 ml. anti-TMVP containing 60 μg antibody per ml. and challenged with 10 μg TMVP.

Results of the experiments utilizing passive cutaneous anaphylaxis (Table 1) show that intravenous challenges with TMVP, $G_{50}S_2$ and D_1, elicited passive cutaneous anaphylaxis with TMVP anti-serum. When injected intradermally with anti-TMVP serum, D_2 and $G_{50}S_2$ inhibited passive cutaneous anaphylaxis on intravenous challenge with TMVP. The activity of the tryptic peptides was specific to the TMVP–anti-TMVP system since the $G_{50}S_2$, D_1 or D_2 did not affect passive cutaneous anaphylaxis with the lysozyme–anti-lysozyme system.

The results indicate definitely that at least one of the tryptic peptides possesses immunological properties related to those of TMVP. Assuming that under the conditions of dialysis one or more of the peptides was completely non-dialysable, the results suggest the presence of two immunologically active peptides. However, the possibility exists that conditions used during dialysis caused one or more of the peptides to be in equilibrium between its polymerized and non-polymerized form, resulting in the same peptide or peptides being present both in D_1 and D_2. From investigations with isolated muscle strips, it appears that both D_1 and D_2 fractions can combine with the antibodies of the TMVP-sensitive ileum. The passive cutaneous anaphylaxis experiments indicate that, at the concentrations used, at least one of the peptides present in the non-dialysable fraction elicits passive cutaneous anaphylaxis, while at least one peptide present in the dialysable portion inhibits the reaction.

Table 2. Effect of TMVP, $G_{50}S_2$, D_1, D_2, and Histamine on Isolated Guinea Pig Ileum Strip as determined by the Schultz–Dale Technique

Ileum source	Initial treatment			Subsequent treatments*			
	Material	Final concentration†	Result	TMVP added†	Result	Histamine added†	Result

* Added to the system following relaxation from preceding treatment.
† All figures represent final concentration in mg/ml.
‡ No. of plus signs indicate approximate magnitude of contraction.

The $G_{50}S_2$ fraction was dialysed in the cold against distilled water which was adjusted to *p*H 7·0 with ammonia. The non-dialysable portion (D_1) and the dialysate (D_2) were lyophilized. D_1 and D_2 gave a distribution of absorbency at 280 mμ of 51 and 49 per cent respectively.

The antigenic activity of the peptides was determined by direct passive cutaneous anaphylaxis according to the method of Ovary[14]. Antisera against TMVP were obtained by immunizing rabbits with TMVP and adjuvants. The sera were pooled and contained 3 mg antibody per ml. The antibodies were injected intradermally in 0·1 ml. M/15 phosphate buffer *p*H 8·0. Three hours later TMVP or the peptides were injected intravenously in 1 ml. of 0·25 per cent Evans's blue in buffer. When passive cutaneous anaphylaxis inhibition was studied, the peptides were added to the antibodies and a total volume of 0·1 ml. was injected intradermally; TMVP was injected 3 h later. The specificity of the reactions observed were tested using a lysozyme–antilysozyme system. Results are shown in Table 1.

The activity of the peptides was also determined by the Schultz–Dale technique[15] using isolated ileum strips from guinea pigs sensitized to TMVP. The ileum strips were approximately 1 in. long, immersed in 8 ml. Tyrode's solution at *p*H 7·2, and maintained at 37° C. The test material was added in 1 ml. Tyrode's solution. Results are shown in Table 2.

The results show that tryptic peptides of TMVP possess immunological properties. Using the Schultz–Dale technique, TMVP, $G_{50}S_2$, D_1 and D_2 caused contractions (Table 2). At the concentrations used, the contraction elicited by TMVP was not inhibited when TMVP was added to the system containing $G_{50}S_2$, D_1 or D_2. TMVP and $G_{50}S_2$ were not active when tested on ileum not sensitive to TMVP.

After the manuscript of the present communication was prepared, we noted the report by Anderer[16] in which a C-terminal hexapeptide of TMVP was correlated with some of the antigenic activity of the tobacco mosaic virus.

We thank Drs. C. A. Knight and G. Funatsu of the University of California Virus Laboratory, Berkeley, for supplying tobacco mosaic virus and for help in the ion exchange chromatography, respectively.

FORTHCOMING EVENTS

Wednesday, August 28—Wednesday, September 4

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE (at Aberdeen)—125th Annual Meeting.

Wednesday, August 28

At 7.30 p.m.—Sir Eric Ashby, F.R.S.: "Investment in Man" (Presidential Address).

Thursday, August 29

At 10 a.m.—Prof. J. Monteath Robertson, F.R.S.: "A Physical Approach to Chemical Structures" (Presidential Address, Section B).

At 10 a.m.—Dr. F. Fraser Darling: "The Unity of Ecology" (Presidential Address, Section D).

At 10 a.m.—Dr. S. G. Hooker, F.R.S.: "Future of the Aeroplane in Civil and Military Fields" (Presidential Address, Section G).

At 10 a.m.—Prof. J. McMichael, F.R.S.: "The Contribution of Clinical Medicine to Physiology" (Presidential Address, Section I).

At 10 a.m.—Dr. T. P. Morris: "Science and Morals in the Treatment of Deviant Behaviour" (Lister Lecture).

At 11.20 a.m.—Sir Charles Morris, K.C.M.G.: "Personal Values in Education" (Presidential Address, Section L).

At 11.30 a.m.—Prof. W. J. H. Sprott: "Problems of Penology" (Presidential Address, Section N).

At 2.30 p.m.—Sir Raymond Priestley: "Antarctic Exploration Yesterday and To-day" (York Lecture).

riday, August 30

At 10 a.m.—Dr. J. S. Forrest: "High Voltage Insulation" (Presidential Address, Section A).

At 10 a.m.—Prof. H. C. Darby: "British National Parks" (Presidential Address, Section E).

At 10 a.m.—Mr. E. J. H. Corner, F.R.S.: "The Tropical Botanist" (Presidential Address, Section K, K*).

At 10 a.m.—Prof. Martin Jones: "Providing Food for Man and Beast" (Presidential Address, Section M).

At 11.30 a.m.—Prof. O. L. Zangwill: "Cerebral Localization of Psychological Function" (Presidential Address, Section J).

At 11.30 a.m.—Prof. D. J. Robertson: "The Present Position of the City" (Presidential Address, Section X).

At 8 p.m.—Prof. C. F. Carter: "Problems of Economic Growth" (Evening Discourse).

Sunday, September 1

At 11 a.m.—Service in the West Church of St. Nicholas, Union Street. Minister: The Reverend Anderson Nicol, M.A., J.P. Preacher: The Reverend Prof. John M. Graham, D.D.

Monday, September 2

At 10 a.m.—Prof. J. H. Taylor, F.R.S.: "Some Aspects of Diagenesis" (Presidential Address, Section C).

At 10 a.m.—Prof. T. Wilson: "The Price of Growth" (Presidential Address, Section F).

At 10 a.m.—Mr. Peter Opie: The Tentacles of Tradition" (Presidential Address, Section H).

At 10.10 a.m.—Prof. H. M. Steven: "The Beneficent Forest" (Chairman's Address, Section K*).

At 2 p.m.—Dr. J. N. Murrell: "Colour and Chemical Constitution" (Kelvin Lecture).

Wednesday, September, 4

At 10 a.m.—Dr. L. Wolpert: "Growing in a Definite Shape" (Darwin Lecture).

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER (with a degree or equivalent qualifications, and teaching and/or industrial experience) mainly for PHYSICS and ELECTRONICS, to teach at various levels to National Certificate and Higher National Diploma classes—The Principal, R.R.E. College of Electronics, Royal Radar Establishment, Malvern (August 28).

TEMPORARY LECTURER or TEMPORARY ASSISTANT LECTURER (preferably with interests in the biology of fish) IN MARINE BIOLOGY—The Registrar, University College of North Wales, Bangor, North Wales (August 29).

LECTURER IN REFRACTORIES AND CERAMIC TECHNOLOGY—The Registrar, The University, Sheffield (August 31).

SENIOR LECTURER IN THE COMPUTING LABORATORY—The Secretary of University Court, The University, Glasgow (August 31).

RESEARCH STUDENT IN APPLIED PHYSICS—The Registrar, The University, Hull (September 1).

LECTURER IN ANIMAL PATHOLOGY in the School of Veterinary Medicine, for duties which include teaching and research—Dr. T. D. Kellaway, Secretary of the Appointments Committee, Department of Pathology, The University, Tennis Court Road, Cambridge (September 6).

SENIOR LECTURER and a LECTURER (with an honours degree in mathematics, and preferably a higher degree, and some experience of research) IN MATHEMATICS at the University of Queensland, Brisbane, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, September 6).

EXPERIMENTAL OFFICER IN THE DEPARTMENT OF CHEMISTRY in the Faculty of Sciences, to be concerned with preparative work involving the synthesis of inorganic molecules containing isotopically labelled atoms—The Registrar, The University, Manchester 13 (September 7).

LECTURER IN ANALYTICAL CHEMISTRY—The Staff Officer, College of Advanced Technology, Gosta Green, Birmingham 4, quoting Ref. 8/63/6 (September 9).

LABORATORY TECHNICIANS (2) IN PHYSIOLOGY—The Registrar, University of New South Wales, Armidale, New South Wales, Australia (September 13).

FELLOW (with a Ph.D. degree in physics or metallurgy, or research experience of an equivalent standard and duration, supported by satisfactory evidence of research ability) IN METAL PHYSICS IN THE DIVISION OF TRIBOPHYSICS, Commonwealth Scientific and Industrial Research Organization, Melbourne, Australia, to join a group studying the properties of defects in crystals—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 370/153 (September 14).

RESEARCH OFFICER or SENIOR RESEARCH OFFICER (with a Ph.D. degree in an appropriate field or postgraduate research experience in physics of equivalent standard and duration supported by satisfactory evidence of research ability) IN THE DIVISION OF PHYSICS, National Standards Laboratory, Commonwealth Scientific and Industrial Research Organization, Chippendale, New South Wales, Australia, to undertake research into new and improved methods of measuring temperature—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 770/257 (September 14).

SENIOR LECTURER IN CHEMICAL PATHOLOGY to undertake duties primarily teaching and research—The Secretary, St. Thomas's Hospital Medical School, London, S.E.1 (September 14).

ASSOCIATE PROFESSOR or LECTURER/SENIOR LECTURER IN THE DEPARTMENT OF FARM MANAGEMENT within the Faculty of Agricultural Economics, University of New England, Armidale, New South Wales, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 15).

LECTURERS or ASSISTANT LECTURERS (2) IN THE DEPARTMENT OF GEOGRAPHY, University of Malaya—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Malaya and London, September 15).

LECTURER or ASSISTANT LECTURER (preferably pure mathematician) IN MATHEMATICS—The Secretary, The University, Aberdeen (September 16).

MAP CURATOR (with a good honours degree in geography and preferably appropriate library experience)—The Registrar, The University, Hull (September 16).

LECTURER or SENIOR LECTURER (qualified by training and experience to help in the teaching of general invertebrate zoology and some special aspect of physiology, preferably of invertebrate animals) IN ZOOLOGY at the University of Adelaide, Adelaide, South Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, September 20).

LECTURER/SENIOR LECTURER (preferably with experience in radiochemistry and/or radiation chemistry) IN PHYSICAL CHEMISTRY at the University of Sydney, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 20).

SENIOR LECTURER IN CHEMICAL PATHOLOGY—The Registrar, The University, Sheffield (September 21).

LECTURER/SENIOR LECTURER IN BIOLOGY in any field of animal biology at the University of Sydney, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 23).

PHYSIOLOGIST, for metabolic studies in the Pig Laboratory—The Secretary, Institute of Animal Physiology, Agricultural Research Council, Babraham, Cambridge (September 23).

PROFESSOR OF EXPERIMENTAL PHYSICS at the University of Adelaide—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, September 30).

PROFESSOR OF INORGANIC CHEMISTRY at the University of Adelaide, Adelaide, South Australia—The Secretary, The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, September 30).

READER (with appropriate academic qualifications and teaching experience) IN PHILOSOPHY at the University of Hong Kong—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, September 30).

CHAIR OF PHARMACOLOGY—The Registrar, University of Newcastle upon Tyne, 6 Kensington Terrace, Newcastle upon Tyne 2 (October 12).

ELECTRON MICROSCOPIST (with at least a B.Sc. in physics or life sciences, and preferably previous experience of electron microscopy), to take charge of the New Zealand Medical Research Council's Electron Microscope Unit at the University of Otago Medical School, Dunedin—The Secretary, The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or The Administrative Office, New Zealand Medical Research Council, Box 913, Dunedin, New Zealand (Dunedin, October 12).

CHAIR OF BIOCHEMISTRY at Lincoln College, University of Canterbury, New Zealand—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, October 31).

CHAIR OF HORTICULTURE at Lincoln College, University of Canterbury, New Zealand—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, October 31).

PROFESSOR OF ENGINEERING at Newcastle University College, The University of New South Wales, Australia—The Agent-General for New South Wales, 56 Strand, London, W.C.2; and The Appointments Section, The University of New South Wales, Box 1, Post Office, Kensington, New South Wales, Australia (October 31).

ASSOCIATE PROFESSOR (preferably candidate working on the integrative aspects of mammalian physiology, especially in the neuroendocrine, gastrointestinal or cardiovascular fields) IN PHYSIOLOGY—Prof. J. W. Pearce, Department of Physiology, Faculty of Medicine, University of Alberta, Edmonton, Alberta, Canada.

DEMONSTRATOR, to give laboratory instruction in plant physiology and general botany—Head, Department of Biology and Botany, University of British Columbia, Vancouver 8, B.C., Canada.

ELECTRON MICROSCOPIST (scientifically or medically qualified, interested in furthering technical aspects of electron microscopy with reference to general biological problems, and preferably with previous biological experience) IN THE ELECTRON MICROSCOPY DEPARTMENT, to take charge of the work—The Secretary, Lister Institute of Preventive Medicine, Chelsea Bridge Road, London, S.W.1.

FIELD ZOOLOGIST (male, single, with a university honours degree in zoology, an interest in ornithology, and preferably some research and/or teaching experience) for the post of Assistant Warden at Flatford Mill Field Centre

—The Warden, Flatford Mill Field Centre, East Bergholt, near Colchester, Essex.

Graduate in Physiology, Zoology or related sciences, for work with experimental animals in the field of toxicology—The Administrative Officer, Huntingdon Research Centre, Huntingdon.

Graduate Physicist (preferably with previous experience in hospital physics, but candidates graduating this summer may apply) in the Radio/Therapy Department, to assist with radioactive isotope studies—The Personnel Officer, St. Thomas's Hospital, London, S.E.1.

Lecturer (with a good honours degree and preferably teaching and/or industrial experience) in Physics, to teach physics and applied physics to H.N.D. and Grad. Inst. P. level—The Principal, Mid-Essex Technical College and School of Art, Market Road, Chelmsford, Essex.

Mathematician-Programmer (with an honours degree in mathematics from a recognized university, and preferably with a higher degree and possessing experience in programming and numerical analysis) at the National Research Council Computation Centre, for duties involving the analysis and programming of problems originating in the various scientific and engineering divisions of the Council, and possibly the supervision of junior programmers—The Employment Officer, National Research Council, 100 Sussex Drive, Ottawa 2, Canada, quoting File ER-282.

May and Baker Scholar (with a good honours degree in chemistry, biochemistry or botany), for research on the mode of action of herbicides at the sub-cellular level—Prof. E. O. Morris, Department of Applied Microbiology and Biology, Royal College of Science and Technology, Glasgow.

Pharmacologist or Physiologist (with an honours degree), to study active polypeptides in acute parasitic infections—The Administrative Secretary, School of Tropical Medicine (University of Liverpool), Pembroke Place, Liverpool 3.

Physical Chemist—The Dean, Faculty of Science, Haile Sellassie I University, P.O. Box 399, Addis Ababa, Ethiopia.

Research Assistant (with a good honours degree in a biological subject, and preferably research experience in human or animal cytogenetics and/or some field of tissue culture; recent graduate with no research experience may also apply) in the Cytogenetics Group of the Paediatric Research Unit—The Secretary, Paediatric Research Unit, Guy's Hospital Medical School, London Bridge, London, S.E.1.

Research Fellow (with a degree in chemical or mechanical engineering, metallurgy, chemistry or physics) in the Department of Metallurgy, for research on the engineering principles which underlie processes used for metal extraction and refining—Prof. F. D. Richardson, Metallurgy Department, Imperial College of Science and Technology, London, S.W.7.

Research Fellows (with a Ph.D. with experience in carbohydrate, phosphorus, or nucleic acid chemistry, in enzymology, or in the intermediate metabolism of nucleotides), to participate in studies in the biochemistry of neoplasia—The Director, University of Alberta Cancer Research Unit, McEachern Laboratory, Edmonton, Alberta, Canada.

Senior Physical Chemist interested in examining the properties of new protein derivatives and in applying the Flory polycondensation theory to some new reactions; and a Senior Development Chemist, to investigate uses for the new derivatives—The Director of Research, The Gelatine and Glue Research Association, 2A Dalmeny Avenue, Holloway, London, N.7.

Senior Technician (Grade I or II) in Biochemistry at the Midland Centre for Neurosurgery and Neurology, Holly Lane, Smethwick—The Group Secretary, West Bromwich and District Hospital Management Committee, West Bromwich and District Hospital, West Bromwich.

Senior Technician (with H.N.C. in chemistry or equivalent, experience in general laboratory procedure and a genuine interest in analytical biochemistry), for chemical and clinical research in a newly created steroid laboratory of the Medical Research Council Unit of Neuroendocrinology—The Administrator, Department of Human Anatomy, The University, South Parks Road, Oxford.

Superintendent (with a degree in biological science or equivalent qualification, for example, F.A.T.A., and experience in some branch of animal work), to take charge of the Physiology Department's goat and small animal house—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, Berks, quoting Ref. 63/2.

Technician for the Department of Animal Husbandry—The Assistant Secretary, Royal Veterinary College, Royal College Street, London, N.W.1.

Technician or Senior Technician, to be responsible for the technical servicing of a zoological laboratory—The Dean of the School of Biological Sciences, University of East Anglia, Earlham Hall, Norwich, NOR 05G.

BIOCHEMISTRY

Quantitative Spectrophotometric Determination of Indolyl-3-acetic Acid.—R. A. Fletcher and Saul Zalik 903

A New Reticuloendothelial System Stimulating Agent ('Restim') from Shark Livers.—Dr. John H. Heller, Varsenig Z. Pasternak, John P. Ransom and M. S. Heller 904

A New Metabolic Regulator: its Stimulation of Citric Acid Production and Anti-sulphonamide and Streptomycin Effect.—Dr. Z. Fencl and E. Vintrová 905

In vivo Degradation of Histamine-adenine Dinucleotide Phosphate to Histamine Ribonucleoside.—Prof. S. G. A. Alivisatos, A. A. Abdel-Latif, F. Ungar and G. A. Mourkides 907

Occurrence of Two Different Enzymes in the Silkworm, *Bombyx mori*, to reduce Folate and Sepiapterin.—Masako Matsubara, Motoo Tsusue and Miki Akino . 908

Microbial Degradation of Cephalosporin *C*.—Arnold L. Demain, Robert B. Walton, Joanne F. Newkirk and Ian M. Miller 909

PHYSIOLOGY

Evidence of the Mechanism of Ouabain Inhibition of Cation Activated Adenosine Triphosphatase.—Dr. J. S. Charnock and Dr. R. L. Post 910

Polystyrene Membranes for Covering Oxygen Electrodes for Use in Tissue.—P. F. D. Naylor and N. T. S. Evans 911

Stereochemical Theory of Olfaction.—B. Fullman; Dr. J. E. Amoore 912

A Metabolic Regulating Device based on the Actions of Human Growth Hormone and of Insulin, Singly and Together, on the Human Forearm.—Dr. David Rabinowitz and Prof. Kenneth L. Zierler . . 913

Page

Photodynamic Effect of Diidroquinidine on Isolated Hearts of Mammals.—Dr. G. Pace and Dr. W. Pierpaoli 915

PHARMACOLOGY

Antitussive Activity of a New Local Anæsthetic Compound: Benzobutamine.—G. Maffii, B. Silvestrini and S. Banfi 916

Potentiation of the Anti-reserpine Effects of Dihydroxyphenylalanine by Antidepressants and Stimulants.—Dr. W. R. McGrath and H. J. Ketteler 917

HÆMATOLOGY

Hæmoglobins of Two Elephant Shrews.—Prof. John Buettner-Janusch and Vina Buettner-Janusch . 918

Sedimentation Characteristics of the Human Hæmoglobins A, F and E.—Pankaj Ganguly, Dr. N. N. Das Gupta and J. B. Chatterjea 919

PATHOLOGY

Effect of Thymectomy on the Induction of Skin Tumours by 3,4-Benzopyrene.—Dr. J. F. A. P. Miller, Dr. G. A. Grant and Dr. F. J. C. Roe . . 920

Wine as Source of Iron on Hæmochromatosis.—Prof. Richard A. MacDonald 922

RADIOBIOLOGY

A Fast-neutron Source for Radiotherapy.—Dr. R. J. Berry, R. Oliver and Dr. E. H. Porter; P. D. Lomer and D. Greene; Dr. J. F. Fowler 923

Influence of Fractionation on Clinical Response and Dosage in Radiotherapy.—J. A. C. Fleming and G. Wiernik 924

BIOLOGY

Effect of Certain Soil Organisms on the Eggs of Parasitic Roundworms.—Dr. Hynek Lýsek . . . 925

Influence of Mechanical Damage on Opaline Silica Deposition in *Molinia caerulea* L.—D. Wynn Parry and Dr. Frank Smithson 925

MICROBIOLOGY

Unlinked Loci affecting Related Biosynthetic Steps in *Pseudomonas aeruginosa*.—Dr. B. W. Holloway, Lynette Hodgins and Barbara Fargie . . . 926

Polysaccharide Fractions and Transformations in *Rhizobium*—Prof. Beverley A. Humphrey and J. M. Vincent 927

ENTOMOLOGY

Penetration of Pyrethrin I labelled with Carbon-14 into Susceptible and Pyrethroid Resistant Houseflies.—B. C. Fine, Dr. P. J. Godin and E. M. Thain . . 927

Sound Signals and Alternation Behaviour in *Pholidoptera*.—M. D. R. Jones 928

CYTOLOGY

Corrected Chromosome Numbers for *Spartina* × *townsendii* and its Parent Species.—Christopher J. Marchant 929

Analysis of Tritium-labelled Human Chromosomes and Sex Chromatin.—Mrs. Audrey Bishop and O. N. Bishop 930

GENETICS

Different 'Spectra' of Mutant Types by Extra-cellular Treatment of Phage Kappa with Differing Mutagens.—Prof. R. W. Kaplan, H. Beckmann and W. Rüger 932

PSYCHOLOGY

Electroencephalogram Alpha-activity during Mild Vestibular Stimulation.—Dr. William E. Collins and Dr. Jerome B. Posner 933

INVESTMENT IN SCIENCE THROUGH MAN

SIR ERIC ASHBY's presidential address to the British Association for the Advancement of Science (see p. 877 of this issue) is a fitting complement to that of Sir John Cockcroft's at last year's meeting in Manchester. As Sir Eric observes at the start, the pre-requisites for investment in science are, first, scientists, and secondly, a public opinion sufficiently well informed and enlightened to give financial support to scientists. Both these are acquired through education, and, accordingly, to invest in science we have first to invest in man.

It is not only from Sir John Cockcroft, however, that Sir Eric could have obtained his lead. It is equally to be found in the emphasis placed on investment in education as a factor in economic growth by the National Economic Development Council and earlier still by the Organization for European Economic Co-operation (now the Organization for European Co-operation and Development). Indeed, the glance that Sir Eric gives at the address given in Aberdeen by his predecessor, the Right Hon. Sir Lyon Playfair, in 1885, almost implies an even earlier ancestry, and there may well be readers wishing the president had had the temerity to retail that earlier address in place of his own stimulating, but highly provocative, address. Nevertheless, any recasting of Sir Lyon Playfair's words or annotations on his theme to which Sir Eric Ashby is tempted are unlikely to be less penetrating than the address he actually delivered. However prolonged its conception, the address is entirely contemporary in its thought and exemplifies throughout that respect for the past, acceptance of a rigorous discipline and receptivity of new ideas which he himself proclaims as the unique contribution which universities make to society. He does justice to virtues in Britain's existing institutions which some critics are inclined to ignore, though without allowing any complacency. Indeed, he shatters the idea that Britain can just wait for the Robbins Committee to report as effectively as he makes nonsense of some of the wilder party political proposals. While he brings to the discussion of the plan and functions of the universities a note of urgency and realism which should force the most reluctant common room to think seriously about questions its members might rather leave alone, he never advocates change for the sake of change.

Sir Eric Ashby is concerned in this address essentially with one section only of the problem of investment in education—investment at the level of higher education, and, more especially, with the university as a social instrument for such investment. He raises many pertinent questions, to some of which the Robbins Committee is already seeking answers. Others, it is manifest, require investigations that have not even been initiated, and one purpose of the address appears to be to stimulate such enquiry so that there may be no long delay when the Robbins report appears. Here, however, Sir Eric appears rather to underestimate the attention which is now being given to educational research in Britain. If this is not as yet concerted in any such way as it is under the National Science Foundation in the United States, proposals for an Educational Research Council have already been presented to the Minister for Science; the recent annual report of the Nuffield Foundation indicates a substantial range of work in progress. Sir Edward Boyle's speech in the House of Commons on July 24 indicated that the limiting factor is not the selection of appropriate projects, but finding teams of investigators competent to execute the project, however, admittedly the bulk of such work is still concerned with education in the schools.

First, Sir Eric considers the resources of ability for this section of investment in man, and, after stressing the unreliability of the comparative figures for students and population in different countries which are used in support of arguments as to the inadequacy of provision here for higher education, he remarks that the one feature of the investment of man in higher education which has been studied scientifically merely leads to the conclusion that we could invest a much larger proportion of the age group than we do. Britain's policy for higher education is tenable only on three assumptions: first, that the techniques for selection are efficient and reliable and satisfy social justice; secondly, that the members selected each year for different kinds of full-time higher education are sufficient for the nation's needs; thirdly, that Britain offers acceptable opportunities for part-time further education to those who are not selected. Sir Eric Ashby believes that none of these assumptions is justified.

While, ultimately, the intellectual resources in a population are limited by its genetic structure, there is abundant evidence that inequalities in Britain's society and inadequacies in her educational system, and not genetics, at present limit her investment in man. He describes Britain's system of selection as a system for distributing challenges: attempts are made to select not those likely to profit from higher education, but to select from all these, the candidates to whom it should be offered. Sir Eric rightly suggests that much more information is needed about the success or failure of those rejected. It is in such a context that the suggestion which has already been made for some separate institution of university quality to take the candidates who have failed to obtain entry might be worth examining. Despite his assertion as to the existence of this larger supply of potential university entrants, in support of which he quotes some evidence, Sir Eric does not, however, consider the possibility of Britain's present methods directing to the universities those students whose potentialities would be more fully and effectively developed in other institutions, such as colleges of technology.

The existence of some opinion to that effect is not, however, inconsistent with Sir Eric's rejection of this first assumption. He is in fact critical of the efficiency and adequacy of Britain's system of higher education apart from the universities and, particularly, of the systems of part-time further education integrated with employment. These are the main reasons for regarding as unsound the second and third assumptions on which Britain's policy for higher education is based. The high rates of wastage in part-time study are the fault of a social system which denies to the part-time student an opportunity to learn well.

Nevertheless, Sir Eric does not advocate indiscriminate inflation of the volume of investment in higher education. Such expansion should be based on far firmer knowledge about the pattern of higher education which is likely to be

relevant to the lives the students are to live. It is this knowledge that we should be acquiring, and it is here that Sir Eric Ashby enters his central theme and begins to ask searching questions about the appropriateness of institutions, their methods and functions, their use and obsolescence to the needs of the community they exist to serve.

At their best, Sir Eric Ashby reminds us, universities endow the men and women who pass through them with the capacity to reconcile orthodoxy and dissent. They not only pass on a corpus of knowledge and ideas, but also train students to disclose errors in knowledge and to question ideas. In so far as they also do this, the colleges of technology also are rightly regarded as university institutions; the dichotomy between technological institutions and universities which Sir Malcolm Knox suggested to the Vice-Chancellors of the Commonwealth Universities in welcoming them to St. Andrews is misleading and dangerous. Both alike have to equip their students to cope with the known. Both have also to encourage the critical temperament which alone will enable its possessor to cope with the unknown.

Sir Eric Ashby is on sound ground in suggesting that the unique contribution which universities make to society is to train young people in this dialectic between orthodoxy and dissent, and that any change in the pattern of universities which endangers this function endangers the society which the university serves. This, he remarks, is the real reason why the universities have to combine teaching and research, and why also they must seek to include among their students those who have the combination of temperament and intellect to profit from this particular approach to learning. But, while he adds, quite rightly, that the universities have also the task of training men and women for the professions and that they will largely be judged by the efficiency with which that task is discharged, his words equally apply to the technological institutions. Their work, too, is endangered when attendance at a university becomes a status symbol, and investment in institutions of technology and universities is ultimately determined by the extent to which the public judges they fulfil their function efficiently.

For such reasons it is important that the distinction between technical and technological institutions should be made clearer, and here again the association with such distinction of any suggestion of status should be avoided. The distinction is one of function and, on the part of the student, of capacity also. It might well be better understood if we knew more about the effectiveness of our educational institutions generally, let alone the efficiency of processes of teaching and learning in universities to which Sir Eric Ashby directs attention. Without a sustained programme of research into higher education it is not possible to provide the answers to the essential questions as to the means and instruments by which we should increase our present investment. Even the present annual expenditure on universities of more than £70 million is too high to expect that investment to be forthcoming—with all that is implied in reduced expenditure or investment elsewhere—unless it can be made on assumptions that are known to be valid.

Whatever difference of opinion there may be as to the scale of expansion or the distribution of that expansion as between the universities and the colleges of technology, for example, Britain is already committed to a large expansion of higher education. The uncertain factor is, Where can be found the 8,000 or more teachers that will be required for the universities alone? Sir Eric is of the opinion that in mathematics, science and technology there is good reason to fear either a shortage of teachers or a decline in quality. Whichever option is elected—and both could be forced on us—Sir Eric is undoubtedly right in suggesting that under such conditions the only way to maintain standards in the university is through the use of operational research on the use made of teachers and on methods of teaching. At present we know little, for example, as to the possibilities which the advent of the film, closed-circuit television and the tape-recorder offer in the reduction of the ratio of staff to students. We do not even know what size of small groups is most effective for teaching by discussions. We have not even explored, in the light of the new possibilities that audio-visual aids, for example, offer, how far we can proceed in the direction to which Comenius pointed three centuries ago, of finding a method by which the teachers teach less and learners learn more.

The brief reference, given by Sir Eric Ashby, to the technical devices now at the disposal of the teacher, suggests something of the exciting possibilities which could follow if the university teacher used them to give himself more time for the intimate encounter of discussion which no modern technique can replace—techniques or possibilities which go far to safeguard and encourage the characteristics which the university must always seek to cherish. It is not the unexamined adoption of new methods that Sir Eric Ashby urges: rather he challenges the unproved assumption that we have nothing to learn about the techniques of teaching or the processes of learning. So too, like Prof. B. R. Williams in a recent even more forthright article, he would examine the efficiency with which we use the capital we invest in universities, not merely the design of the laboratories on which the bulk of the expenditure is made, but the assumptions on which this design is based.

In spite of the evidence elsewhere of the value of research into the utilization of laboratories, we do not know the answers to such questions as whether we should continue to build scientific laboratories on the pattern traditional in British universities or whether the capital so invested could now be put to better use; there is little indication that we are attempting to find the answers. Even more important, as Sir Eric justly observes, are the unscrutinized assumptions we make about the function of a university, and in spite of a growing volume of attention to the content of school curriculum, the university curriculum as yet has scarcely been examined from this point of view. There are notable exceptions, it is true, but by and large it is fair to say, as Sir Eric does, that the pattern of courses still presupposes that students are to become professional scientists and scholars, or that students who are not to become professional scientists and scholars should receive the same academic training.

Both these assumptions have in fact been challenged in discussions on the B.B.C. Third Programme, and it may be confidently expected that the Robbins Committee will make some trenchant comments on their validity. There are also untested assumptions about the content of courses, and here Sir Eric makes an important point which he has already expounded at greater length in his book, *Technology and the Academics*—the importance of diffusing technology into the common culture. Education has still to accept technology as a form of humanism.

Finally, Sir Eric attacks the assumption built into Britain's present policy for investment in man that a

three-year undergraduate course is sufficient to set up a man for a life-time. Doubtless that assumption was never or entirely true as Sir Eric implies, for it is fundamentally inconsistent with success in the primary task of a university of imparting a critical and enquiring mind. The student who has learnt to enquire will never entirely lose his or her zest for learning. But the need for measures to combat obsolescence is imperative and urgent.

More is in fact being done than Sir Eric Ashby seems to allow. The professional institutions, like the Roya Institute of Chemistry, as well as the Nuffield Foundation, are already playing a part and the section on education in the latest annual report of the latter body is a fitting counterpart to Sir Eric's remarks on educational research and obsolescence. Nevertheless, as he points out, re-education requires challenge and response, an encounter between teacher and student; what is already being done is on nothing like the massive scale required to meet a need that steadily grows in magnitude as well as complexity. There is perhaps no more important task of higher education than, to use words which Sir Eric Ashby quotes from J. W. Gardner, president of the Carnegie Corporation of New York, to provide a framework within which continuous innovation, renewal and re-birth can occur.

Sir Eric Ashby opened his address with a reference to Sir Lyon Playfair's address in 1885 on the relations of science to the public need. The sub-headings of that address—science and the state, science and secondary education, science and the universities, science and industry, abstract science the condition for progress—cover subjects which are the subject of present-day debate, and despite the changed conditions there is still much truth in many of Sir Lyon Playfair's observations. A Ministry of Education has long since arrived, but the very argument over educational research and the need for a 'Council for Educational Research' illustrates our uncertainty as to how far the responsibilities of such a Minister should extend, though it is clear enough from what Sir Edward Boyle said at Belfast on July 5 that the present Minister would go all the way with Sir Eric Ashby in his call for educational research. But can we be sure that it can no longer be said of the British Treasury that it clings to the view indicted by Sir Lyon Playfair in 1885 that there is a finality in science and in expanding knowledge ?

It would be rash indeed to assert that the nation has really grasped the truth and implications of Sir Lyon Playfair's closing words that abstract discovery in science is the true foundation on which the superstructure of modern science is built, for the sorry tale of frustration and shortsightedness and shortage of finance could scarcely then persist. Moreover, Sir Lyon Playfair himself took as his text some words from the presidential address of his predecessor, the Prince Consort, in 1859: "We may be justified in hoping . . . that the Legislature and the State will more and more recognize the claims of science to their attention, so that it may no longer require the begging-box, but speak to the State like a favoured child to its parent, sure of his paternal solicitude for its welfare; that the State will recognize in science one of its elements of strength and prosperity, to foster which the clearest dictates of self-interest demand". This makes a fitting tail-piece to Sir Eric's address, for just a century later a Minister for Science was appointed, but even so we still await the fulfilment of the hopes of Prince Albert. Moreover, the present debates in both Houses of Parliament, for all the evidence they afford that Sir Eric Ashby's words may fall on fertile ground, do not indicate that there is any real and widespread appreciation of the price that must be paid if Britain is to make the investment in man to which Sir Eric calls, and make that investment wisely and efficiently.

SUPPORT OF RESEARCH IN U.S. UNIVERSITIES AND COLLEGES

The Effects of Federal Programs on Higher Education

A Study of 36 Universities and Colleges. By Harold Orlans. Pp. xvi+361. (Washington, D.C.: The Brookings Institution, 1962.). Paper 2.95 dollars; Cloth 5 dollars.

THIS volume is a carefully documented survey of the effect of U.S. Federal expenditure in the Universities and colleges. Although the university system is so different from that in Britain, surveys of this kind are of immense value to those interested in similar problems in the U.K. There is much to be learned from this survey since some well-defined tendencies in Britain are along lines pursued in the United States for many years. The total expenditure by Federal Government, both from civilian and defence agencies, is no less than 1,000 million dollars a year. The report does not state what the total cost of running all the universities and colleges in the U.S. amounts to, and thus it is impossible to estimate what fraction comes from Federal funds. However, in some of the leading institutions it is known that 50 per cent of their income is derived in this way.

It would clearly be impossible to do this kind of job other than by taking representative samples from State and private universities and liberal arts colleges. This is done by examining twelve institutions of each type, and the general results are given in tabular form in the report so that it is easy for the reader to examine for himself whether the right conclusions have been drawn.

Commenting on the quality of staff, and on the teaching done, the clear conclusion is that these have not suffered. In fact, rather the opposite is true, for these funds have enabled the institutions to retain staff of high quality in spite of the strong recruiting drives from U.S. industry. Generally the smaller institutions with smaller contributions from Central Government funds fare worse. Their staff salaries are lower and their teaching load is higher. The result naturally is that even more funds go to the bigger institutions. In this struggle the private universities fare best. The result is that research as such is regarded as a prestige occupation and teaching something to be done by others, particularly at a lower level. One might therefore wonder how students of ability receive a good education if the leaders in science do not take some part in it. Maybe, the answer is that with high student mobility, the better class institutions can pick and choose with care and so succeed eventually in getting the best brains into their graduate schools.

One of the most surprising facts elucidated in the survey is that this vast sum of money does not necessarily induce the best brains to take a science training. The arts and social sciences get their full share of what is going. It has even been possible to gain some idea of where the best students go. At undergraduate level the liberal arts colleges top the list. In the graduate schools the order is private universities with large federal funds, private universities with small federal funds, public universities with large funds, and public universities with small funds. Thus money itself does not necessarily attract the best. One noticeable result clearly shown is that there is a tendency for professors, in the American sense, to do less teaching of undergraduates. In fact 12–18 per cent of the staff do no undergraduate teaching at all, though it must

be remembered that graduate teaching is far more developed than it is in the U.K., and that the first degree in science is taken at a lower level than it is in Britain.

The report itself is critical of the way in which the funds are dispersed leading to a wider and widening difference in quality between the top and the bottom. On the whole the agencies responsible for providing the funds take the view that their money must be most effectively spent and therefore the better institutions are more favoured. All this can lead to the business of grantsmanship on a really big scale, particularly so when the salary of a member of staff may partially depend on his personally getting support from the agencies.

There is so much information in the report that it is impossible to comment completely, but since the United States is more inclined to engage in experiments of this kind than we do in Britain, it is extremely valuable to have the results of such a survey so that we in Britain may have the benefit of the effect of these methods of working in determining our own domestic programmes and in avoiding errors of judgment which can become of great academic importance. H. W. Melville

A JUBILEE TRIBUTE

Community of Universities

An Informal Portrait of the Association of Universities of the British Commonwealth 1913–1963. By Sir Eric Ashby. Pp. viii+118. (London: Cambridge University Press, 1963.) 12*s*. 6*d*.

THIS slim but important volume was written to herald the ninth quinquennial Congress of the Association of Universities of the British Commonwealth (held in London in July) and in anticipation of the granting of a Royal Charter to the (renamed) Association of Commonwealth Universities. Though based on such records as were not destroyed in 1940, it is not strictly an 'official' history and is refreshingly free from the pious and arid pedantry which often mar such works.

The main purpose of the book is to trace the development of the organization under its different names from the conference convened by Gilbert Parker, member of parliament for Gravesend, in the rooms of the Royal Society in 1903 when it was resolved that: "it is desirable that such relations should be established between the principal teaching universities of the Empire as will secure that special or local advantages for study, and in particular for post-graduate study and research, be made as accessible as possible to students from all parts of the King's Dominions". The first Congress of the Universities of the Empire was held in 1912, a Universities Bureau established, and the publication of a *Yearbook* undertaken. The early years were not without growing pains; yet it was under the auspices of the Bureau that in 1917 a conference commended to the universities 'as a basis for common action' the desirability of establishing the Ph.D. degree.

Even as late as 1931 fears were expressed that the organization might attempt too much in the way of a regimentation of the universities. To-day, the Association is a thriving institution which enjoys the confidence of the universities and is recognized by them as indispensable. The latest edition of its *Yearbook* runs to 1,825 pages and is a major work of academic reference (see *Nature*, 199, 316; 1963); the Association assists in the making of more than 900 overseas appointments annually; it plays a big part in the administration of the scholarship schemes of the Marshall Aid Commemoration Commission and the Commonwealth Scholarship and Fellowship Plan; it organizes the comprehensive quinquennial Congresses, smaller inter-congressional conferences in various parts of the world, and the annual Home Universities Conference; it provides a secretariat for the Committee of Vice-Chancellors and Principals; and, not least, its office in Gordon Square is the Mecca to which the steps of countless academic visitors are directed whenever help and advice are needed.

For many readers a particularly interesting chapter will be the one on the Vice-Chancellors' Committee, a body about whose casual origins and present functions Sir Eric provides much invaluable information. Occasional meetings of groups of Vice-Chancellors or Principals can be traced back as far as 1887. It was a simple matter of convenience that the Vice-Chancellors of the home universities were appointed in 1910 as a committee of the Bureau to take charge of the academic side of the 1912 Congress; and it was this perhaps that triggered off the proposal of W. M. Childs of Reading in 1912 for 'devising more effective machinery for joint action'. It was, however, a conference at the Foreign Office, convened in May 1918 by A. J. Balfour with the concurrence of H. A. L. Fisher to discuss the Ph.D. question, which really brought the Vice-Chancellors' Committee into being under the auspices of the Bureau. Since that date, the constitutional position of the Committee has several times been clarified and the range of the topics with which it has perforce to concern itself has grown immeasurably. Sir Eric's judgment on its present status and activities is worth quoting: "The Committee to-day is as informal as ever it was. But its influence is very great indeed. It rarely makes pronouncements, but the pronouncements it does make carry great weight. Far from infringing university autonomy the Committee is a powerful instrument for preserving it".

This book is a delight to read, with never a dull page. It has all the pithiness of style, sense of perspective and penetrating comment which we have long come to associate with Sir Eric's writing. The facts are marshalled with an easy mastery and the main themes never obscured. Especially valuable features are the extensive quotations from a number of vital documents (such as Balfour's letter of 1918) not easily accessible otherwise and the succinct summaries and comparisons of the topics discussed at the various Congresses. There are eight short appendixes (including one of brief biographies of some outstanding personalities in the history of the Bureau and the Association) and a short index.

For everyone involved in the work of universities at home or overseas or generally interested in their welfare this book should be regarded as essential reading. The fascinating story it unfolds should inspire in the universities a quiet confidence during the period when they live under the shadow of Robbins and afford them encouragement as they face the glare of whatever 'new deal' may await them. James Mountford

UNITS OF EVOLUTION

Animal Species and Evolution

By Prof. Ernst Mayr. Pp. xiv+797. (Cambridge, Mass.: The Belknap Press of Harvard University Press; London: Oxford University Press, 1963.) 70*s*. net.

THIS is a magistral book. It is certainly the most important study of evolution that has appeared for many years—perhaps even since the publication of *The Origin of Species* in 1859.

In any event, it resembles the *Origin* in focusing on the species as the key to evolutionary understanding. The species concept is certainly central, as Mayr shows in his chapter on the history of the subject. He reminds us that Darwin considered it a purely arbitrary one: "I look at the term as one given for the sake of convenience to a set of individuals closely resembling each other". For him the species had no objective existence. His prime concern was to show that they were not fixed, but could be "transformed"—in other words, evolve. Lin-

næus, through his emphasis on the essential distinctness or "fixity" of species, with its implications of their non-arbitrary nature, was able to defeat what Mayr calls "the folklore belief of the easy mutability of species", and for the first time posed the scientific problem of their origin.

The central thesis of Mayr's book, supported by a vast array of facts from every field of biology, is that species are *not* arbitrary creations of the taxonomist, but objective entities—the units of evolution, to be recognized by their distinctness rather than the degree of their difference. Furthermore, they are highly organized entities. Far from being just an agglomeration of separate mutations, or a mere collection of variant individuals, they are populations with a closely knit genetic structure, an integrated and cohesive gene-pool, homeostatic and change-resistant. This is a repudiation of the "beanbag" view, as Mayr calls it, which was in vogue in the early years of genetics. In the modern view, genes are not isolated entities with fixed properties; the selective value of a gene differs both in relation to genetic background and to environmental conditions. Although the ultimate source of evolutionary novelty is mutation, by far the largest immediate source is genetic recombination.

From these principles and from the vast body of taxonomic fact, certain conclusions follow. The most important is that we have to do something which Darwin never attempted—namely, to distinguish two very different methods of "transformation of species" or evolution—on one hand, phyletic evolution, resulting from the internal transformation of a single species, and on the other hand what Mayr calls "true speciation", the splitting of one original species into two. The long-term continuation of such splitting underlies the major evolutionary process of branching taxonomic differentiation and consequent adaptive radiation to which Rensch has given the useful name of 'cladogenesis'.

Internal transformation of species is of course widespread. It is correlated with spatial and temporal differences in the environment, and its results are manifested in the population structure of the species, notably by its network of adaptive clines, its genetic polymorphisms, and its geographical differentiation into subspecies. In the long term, internal phyletic change may so transform a population that it merits being categorized as a new species: this has been demonstrated in fossil echinoderms and a few other lineages.

The most interesting result of Mayr's analysis is the demonstration of the difficulty and rarity of true or multiplicative speciation. The cohesion and integration of the gene-pool of a species is so high, its genetic and epigenetic homeostasis so considerable, the pressure of gene-flow within the interbreeding unit so great, as to make it virtually impossible for a new integrated genetic pattern to arise within it. This applies even to peripheral parts of the species range, where environmental conditions are different, so that density-independent factors often become more important than density-dependent ones: the old cohesion is too powerful to be overridden by the new selection-pressures. However, there is one exception—the situation where peripheral populations become effectively isolated from the main body of the species. There is then no pressure of gene-flow from the co-adapted centre, so that the new selective pressures from the distinctive environment can take over and remodel the genotype to become the basis of a new species-unit.

For various reasons, this radical genetic reorganization may involve very little remodelling of phenotypic appearance. We then have a pair of sibling species. Mayr gives numerous examples and concludes that so-called "biological races" are in reality true but sibling species.

After a masterly review of the geographical differentiation of populations, in which he dismisses drift as unimportant, but puts in a plea for the founder principle, Mayr makes out a strong case for believing that, in animals at least, geographical (spatial) isolation is a prerequisite for cladogenetic speciation. The only exception is that forms with exceedingly specialized ecological requirements, such as monophagy, may possibly speciate without benefit of geographical isolation.

He is careful to point out that subspecies do not have the same objective reality as species: they are not evolutionary units of the same kind as (but on a lower taxonomic level than) species. On the other hand, the concept of the subspecies is an important taxonomic tool which in the hands of competent systematists can throw much light on the problems of intra- and trans-specific differentiation.

In this field, comparative taxonomy is beginning to give interesting quantitative results. Thus there are about 8,600 species and 28,500 sub-species of birds, giving an average of 3·3 subspecies per species. The figure varies from family to family, being low (2·6) in swallows and high (5·1) in larks. In Tiger-beetles the subspecies/species ratio is about the same as in birds, but in small rodents and especially in tropical land-snails it is considerably higher.

For many general biologists, the most novel part of Mayr's book will be his chapters on the genetic organization of populations: "The Population, its Variation and Genetics"; "Factors Reducing the Genetic Variation of Population"; "Storage and Protection of Genetic Variation"; "The Unity of the Genotype" (with a full discussion of pleiotropy, genic interaction, and correlated characters); and the "Population Structure of Species".

One of the most surprising evolutionary discoveries of recent years is that wild species, far from being genetically uniform, contain a vast reservoir of variability, some overt, some concealed or stored but capable of being released in response to selective pressures.

This store of variability includes recessive mutants, isoalleles, and the huge array of morphs involved in balanced genetic polymorphism, both phenotypically conspicuous and cryptic. One important conclusion is that correlated responses in other characters to selection for one character are not only widespread but often deleterious (for example, decreased fertility and viability in response to selection for changed bristle-number in *Drosophila*, or for commercial qualities in domesticated turkeys). A further consequence is the impossibility of accumulating more than a certain number of variability-storing mechanisms (such as heterotic combinations, balanced morphisms, supergenes, and co-adapted gene-systems) in a single gene-pool: this is illustrated by such facts as the narrowness of secondary hybridization belts, and the conversion of heterozygous advantage into disadvantage in double heterozygotes.

In regard to the complex subject of polymorphism, I feel that Mayr has not sufficiently stressed the biological value of sharp morphisms in enlarging the organism's effective niche, and the consequent necessity for establishing a strong bond between the alternative genes concerned in sharp balanced morphisms, so as to avoid one or other being lost through sampling accidents. Nor has he mentioned those cases where diversity is advantageous *per se*, in impeding recognition by predators, as in some grasshoppers and various shallow-water bottom-living marine organisms like bivalve molluscs. In the next edition of his book, he will doubtless take more account of allotypy—the fact that most or all polynucleotides, polypeptides and polysaccharides, at least in higher vertebrates, exist in a large number of chemical forms, the differences of which range from large to extremely slight. Recently a cytogenetic mechanism has been suggested which would account for the frequency of such allotypic mutations. It may be suggested that allotypic mutants of considerable extent will either be eliminated, or utilized in establishing balanced morphisms of the classical type (as in thalassemia or the major blood-groups), whereas

those the effect of which is very small will not be subject to selective pressures and will persist and accumulate, thus increasing the flexibility of the gene-complex.

Here I must bring up the topic of 'fitness'. It is now fashionable among population geneticists to define fitness solely in terms of differential reproductive advantage, without reference to phenotypic fitness involving differential individual survival. Although Mayr repeatedly stresses that selection acts on the phenotype, and that all characters are the result of compromise between different kinds of selection-pressure, his general adoption of this terminology tends to confusion. Of course, the efficacy of natural selection can only be measured in terms of differential reproduction. But the kind of biological fitness (or improvement, to use Darwin's term) which it promotes depends on the kind of selection which is operating. The confusion can only be clarified by redefining the problem in terms of selection, as J. B. S. Haldane and R. A. Fisher have already suggested, and as Darwin himself adumbrated by proposing sexual selection as a separate selective agency. It then becomes clear that two distinct modes of selection are operating in Nature—survival selection involving differential survival of individuals and reproductive selection involving differential production of offspring.

In the process of biological evolution, survival selection is the more important. It produces evolutionary effects because, as Darwin pointed out: (1) the majority of individuals which survive to maturity will leave offspring; (2) the phenotypic variance promoting individual survival has a considerable genetic basis.

Reproductive selection seems to have few biological results beyond promoting optimum progeny-number and efficient mating mechanisms, except where, as in polygamous birds and mammals, there is intense intrasexual competition and therefore a high premium on mating success. In man, on the other hand, differential reproduction is becoming increasingly important, but survival selection is becoming increasingly relaxed, with serious dysgenic consequences.

I have no space to discuss Mayr's interesting views on developmental homeostasy and canalization, or on the limitations imposed on evolutionary possibilities by the organized structure and mode of action of the genotype, except to say that I think he underrates the importance of Waddington's discovery that Lamarckian inheritance can be simulated by "genetic assimilation". I also feel that he underrates the consequential effects of differential growth (allometry). Although genetic patterns of allometric growth can be modified by selection, they still have marked evolutionary effects, as in the well-known cases of horn-development in deer, titanotheres and other mammals. The most important of such consequential effects is the increase of 'intelligence' and other behavioural capacities with absolute body-size, which, as Rensch has demonstrated, depends partly on the differential (allometric) growth-rate of the 'higher' and later-evolved regions of the brain.

I must pass to Mayr's two final chapters. That on "Man as a Biological Species", besides giving a valuable summary of the latest work on the hominid origins of man, stresses the extreme anatomical and biochemical variability of modern man, as demonstrated by Roger Williams, and emphasizes the adaptiveness of human "racial" differentiation. However, he does not point out the possibility that quite slight genetic differences between races or ethnic groups in mean mental capacity may have considerable effects on psychosocial evolution, though producing a marked increase in the supply of exceptionally capable individuals. He closes with a valuable discussion of eugenics, overpopulation, and the possible dangers of excessive outbreeding.

In the other chapter, he undertakes the important task of extending his biological arguments to trans-specific evolution—the origin of higher categories, convergence, grades, evolutionary potential and limitation, mosaic evolution, preadaptation, and the emergence of new types and evolutionary novelties.

Throughout, he emphasizes the indispensable role of the species. All the new radiations that constitute higher taxa arise from some single new species. However, though every new species is a pioneer, making an evolutionary experiment, the great majority soon reach a dead end. It is the sheer multitude of new species which makes it possible for an occasional one, perhaps only one in a hundred thousand, through chance or circumstance, to give rise to a new Order or Class. However, the key problem of trans-specific evolution is the steady rise in level of organization seen during the entire process, and especially the increased organization and quantitative differentiation of "mind" and awareness—the mental or psychological properties of organisms.

We may hope that within a few years it will be possible to deal with the problem of trans-specific process and progress in the same comprehensive way as Mayr has dealt with the subject of species in evolution. Meanwhile, I unreservedly commend this book to all biologists. It contributes notably to a fuller understanding of the objects of their study—the processes and products of life.

Julian Huxley

THE SUN

The Sun and the Amateur Astronomer

By W. M. Baxter. (Amateur Astronomer's Library, Vol. 3). Pp. 165+24 plates. (London: Lutterworth Press, 1963.) 25*s*.

The Sun

By G. Abetti. Second edition. Translated by J. B. Sidgwick. Pp. 358+149 plates. (London: Faber and Faber, 1963.) 63*s*.

Mr. Baxter's book is the most welcome contribution from a member of the British Astronomical Association to be published for some time. He observes the Sun because he likes to observe the Sun: he is not worried by the fact that sunspots are photographed by professionals as part of their regular duties. For him astronomy is, "a pleasing and satisfying hobby". His sunspot photographs, 25 of which are included, certainly gave me pleasure and proved again the folly of wondering whether or not the independent observer catered for by the British Astronomical Association should worry about doing 'useful' work. Mr. Baxter clearly shows how the Association should provide for the amateur while at the same time retaining the respect it has long held among professional societies but which it is in danger of losing. If I am right, the Association's function is educative in the first instance and, Mr. Baxter, it's secretary, elucidates the use of small telescopes and cameras as they observe the Sun. This is an admirable book for the beginner.

Not content with mere photography, Mr. Baxter also uses a Beck-Thorp direct vision diffraction prominence spectroscope, which he describes in some detail together with illustrations of prominence changes observed by himself. For me personally, the chapter on the spectroscope and the spectrohelioscope is a little disappointing for although much detail is given, enthusiasts would want much more, for example, measurements—size, etc. All would have been forgiven if reference had been made to the detailed constructional data of a spectroscope provided in the booklet by F. J. Sellers, published by the British Astronomical Association. I was also disappointed that, in noting Prof. Ellison's encouragement of the amateur, Mr. Baxter did not illustrate his work with references, photographs or drawings from his published work in the Associations journals.

Apart from some very minor quibbles, such as the inclusion of photographs of galaxies which appear in so many books, some poor diagrams due, rather to size of reproduction than draughtsmanship, a limited bibliography and a 'typical' instead of 'actual' graph of sunspot activity, I feel that Mr. Baxter has achieved his purpose admirably. Perhaps next time he will include a chapter for the amateur radio astronomer, for as yet we have little detailed discussion of this most promising field of enjoyable amateur activity. It is a book which should not only inspire the individual enthusiast but also should be used by schoolmasters for advanced projects taking pupils beyond the laboratory. It is entirely complementary to Prof. Ellison's book, *The Sun and its Influence*.

Also complementary to *The Sun and its Influence*, is the well-known text on *The Sun* by G. Abetti. This is a revision of the second edition already widely reviewed. The revision takes the form of a number of additions to the individual chapters, but contained in one appendix. There is also a short new section on the Sun and cosmic rays. Doubtless this technique has enabled the publishers to produce the book cheaply. It is perhaps worth reminding the reader that *The Sun* contains the most detailed account of solar physics at the descriptive level published in Britain. Further, it contains the unusually large number of 149 plates, most of which are worth including. With the large number of astronomical books on the market I wonder if writers could stop inserting photographs of objects or apparatus which are largely irrelevant. Baxter includes four photographs of distant galaxies—Why not four more of his own photographs or a very detailed layout of a spectroscope? Abetti includes the Jodrell Bank radio telescope and a large dish used in Australia: it would have been better to have inserted a photograph of a rhombic or the Australian solar radio spectrohelioscope. Radio observations of the Sun are not dealt with satisfactorily in this revision. The tables classifying solar radio waves on pp. 314 and 339 are not well explained, a fact which can only be put down to lack of space.

A new edition of *The Sun* ought to have included a detailed chapter on solar radio astronomy. It should not have increased the cost of the book greatly. Indeed, fifteen extra pages come available if the list of illustrations is omitted from the beginning: each one is labelled in the text; this is quite sufficient.

The book is written in a form which makes revision easy and is likely to be a best seller for many years. However, I make one plea for future editions—a better bibliography!

J. HEYWOOD

THINKING ANEW ON MODERN PHYSICS

Understanding Physics Today

By W. H. Watson. Pp. xiii+219. (London: Cambridge University Press, 1963.) 30*s*. 5.50 dollars.

THIS new book by Prof. Watson was stimulated, as he says, by the reprinting of *On Understanding Physics*, written twenty-five years ago, and by a period of philosophical reflexion during the past three years. It is not a text-book on physics in the ordinary sense but a serious discussion on where the physicist stands today in his approach and attitude towards the subject in the light of the advances made in micro-physical phenomena.

The author's basic quest is for an intuitive grasp of atomic existence, and he discusses very fully the relation between atomic and modern physics. His attitude is that physics is not based on any formal philosophy, but depends on training and practice, and on human behaviour that has evolved with the growth of experience in doing physics, a point of view from which very few would dissent.

Throughout the discussion Prof. Watson very cleverly introduces simple analogies to make his points, and to show the confusion into which a student might be drawn, he poses many pertinent questions. For example, in the chapter on atomic existence he asks: "When an electron is detected in a counter, on what grounds are we willing to accept the triggering pulses that actuate the electronic recorder as signifying events in the crystal or gas counter due to the electrons we wish to count?" This and similar questions are certainly thought-provoking, and there is no doubt that Prof. Watson fervently desires that physicists should think deeply on these things, as he undoubtedly has done himself.

The first three chapters of the book are intended to prepare the reader for the basic questions concerning existence, substance, motion and atomic connexion which are discussed in the remainder of the book. As is to be expected, quantum mechanics is well to the fore in the discussion, but the book is not intended to explain this topic or how it is applied; the aim is to look on the mathematical system of quantum mechanics not merely as a mathematical invention but as the reasonable way to represent atoms in the continua of classical physics.

Although it has been said earlier, this is no ordinary text-book on physics, yet, apart from the thought-provoking discussion, there is a wealth of knowledge in every chapter from which the young student can derive great benefit.

Undoubtedly the book is a brilliant piece of work and the discussion developed in a highly successful way; it is well written, and I am convinced that it is the result of very deep and sincere thinking. It should be in the hands of all physicists young and old, for by studying its contents they will certainly be stimulated to think anew.

[The late] T. M. YARWOOD

AFRICAN STRATIGRAPHY

The Stratigraphic History of Africa South of the Sahara

By Dr. S. H. Haughton. Pp. xii+365. (Edinburgh and London: Oliver and Boyd, Ltd., 1963.) 63*s*.

THE geographical, economic and political factors which, to a greater or lesser extent, govern the pace and direction of the development of any branch of science have had a striking influence on the course of geological research in Africa. For obvious reasons less is known about the geology of most of Africa than of the more highly developed countries, but the inaccessibility of some of the literature and the limited number of geologists who are able to work astride political boundaries means that much valuable information, which has already been gathered, is not being used to the full.

One of the organizations which has devoted itself to the dissemination of geological knowledge is the Commission for Technical Co-operation in Africa South of the Sahara. It is fitting that Dr. Haughton who, until recently, was the Commission's international scientific correspondent for geology, should bring together the main features of the stratigraphy of the area, which fell under the ægis of the Commission, into one volume.

The Precambrian accounts for the first nine chapters of the book. Seven of these describe the stratigraphy on a regional basis while the other two discuss general topics. Further chapters are devoted to the Palæozoic; the Karroo System; the Jurassic and Cretaceous Systems; Mesozoic igneous activity; the Tertiary and Quaternary sedimentary rocks; and the Tertiary and Quaternary volcanicity. These groupings may appear surprising to the geologist more accustomed to working in the northern hemisphere, as may the amount of space allotted

to various systems and events. Thus the first half of the book is devoted to the Precambrian, while the following chapter on the Palæozoic occupies only eighteen pages. These features, in a well-balanced book, reflect the contrast between the tectonic behaviour of Africa and Europe in post-Cambrian times. The work is essentially a compilation of facts and in each of the sections the lithologies, thicknesses and distribution of the appropriate rocks are considered region by region. Where an understanding of the distribution and stratigraphy of the rocks is dependent on knowledge of the structure this is briefly outlined. In spite of the emphasis on the summarizing of factual information rather than on synthesis, the book, through its clear presentation and careful arrangement, is very readable and is not likely to be treated solely as a convenient work of reference.

The illustrations are good and on the whole well selected, though the general reader will probably find the locality maps, which show place names rather than geological information, of doubtful value. Perhaps the space could better have been utilized to display some geological maps of wider areas—there is no map covering the whole of the region embraced by the title. Maps showing, for example, the distribution of the Karroo System, or the marine facies of the Jurassic and Cretaceous Systems would be most instructive.

The book is balanced, up to date, clearly written and well produced; it fills a real need at the present time.

R. L. Johnson

MOSQUITOES OF THE SOUTH PACIFIC

The Mosquitoes of the South Pacific (Diptera, Culicidae). By John N. Belkin. Vol. 1: Pp. xii+608. Vol. 2: Pp. ii+412. (Berkeley and Los Angeles: University of California Press; London: Cambridge University Press, 1962.) 160*s*. net the set of two volumes.

THE first of these two very handsome volumes contains the text. The second is devoted to distribution maps and tables and taxonomic figures, mainly of male terminalia, pupæ and larvæ. The descriptive work has been undertaken with great thoroughness and in this respect the book can be taken as fully authoritative. No serious student of Pacific mosquitoes will be able to dispense with it. In recommending it to students of Pacific science in general, however, it must be said that the author's views on a number of subjects are highly personal and would not always command the assent of the majority of mosquito workers.

Taxonomically, Dr. Belkin is a 'splitter'. He distinguishes 12 tribes of true mosquitoes as opposed to the 3 recognized at present by most workers, including Stone, Knight and Starcke, whose world catalogue will probably continue to be followed by the majority. The advantages of consistency are such that the prudent will, probably, also await a decision by these authors regarding the various monotypic and oligotypic subgenera introduced by Dr. Belkin. In brief, it is likely that the system used in this book will be generally accepted as an expression of Dr. Belkin's personal opinion regarding the probable phylogeny of the Culicidae rather than as a universal recipe.

The general sections are too discursive for easy reading. Good points are made here and there but there is much that is uncritical, in particular a disproportionate amount of highly speculative phylogeny, surely unsuited to an authoritative monograph. Too little space is devoted to bionomics. It is true that relatively little work has been done on the biology of Pacific mosquitoes but this is all the more reason for directing the reader to sources of information on the biology of Pacific groups as studied in other areas. The distribution maps seem for the most part to be comprehensive and reliable, but it is noted that the very important *Aedes scutellaris* group is not shown as occurring farther west than the Andamans and Nicobars whereas, in fact, it has certainly been found in the Maldives and it has been recorded, apparently on good authority, from Ceylon. The treatment of disease relationships is cursory to a point at which it could sometimes be misleading. Thus no mention is made of the considerable body of evidence incriminating *Culex annulirostris* as a major vector of Murray Valley Encephalitis.

Nevertheless, whatever its other shortcomings, this book is an outstanding contribution to the descriptive taxonomy of the mosquitoes and the author deserves the gratitude of all of us for the untiring exertions which have made it possible.

P. F. Mattingly

AGRICULTURAL ENTOMOLOGY

Entomologie Appliquée à l'Agriculture

Traité publié sous la direction de Prof. A. S. Balachowsky. Tome 1, Vol. 1: Coléoptères. Pp. xxvii+564. 1962. 132F.; Vol. 2: Coléoptères. Pp. 565–1391. 1963. 162F. (Paris: Masson et Cie.)

PROF. A. S. Balachowsky has planned a monumental treatise on agricultural entomology, dealing with insects and other pests of Europe (excluding Russia), the Middle East, and Africa north of the Sahara. The first 'tome', divided into two volumes, includes 1,392 pages and describes the beetles. The remaining seven parts of the treatise will deal with the other orders of insects, with mites, myriapods, molluscs and (in the final part) with nematodes. Some sixty French-speaking scientists are collaborating in this work. They include not only well-known entomologists, but also many younger workers actively engaged in research.

The beetles of agricultural importance are described family by family. First there is a general description, then an account of the anatomy of all stages from egg to adult. Up-to-date accounts of the results of biological and physiological research are included, with some notes on control. The space given to a family usually reflects its economic importance in Europe; thus about 20 pages are devoted to wireworms and 100 to the Colorado potato beetle. The accounts of stored product pests are rather brief. Descriptions are clearly expressed and well illustrated. These two volumes contain 784 figures, many originals, others copies of well-known, but nevertheless useful, drawings or photographs.

Each volume contains an extensive bibliography, again divided into families. This contains most if not all important references to papers published up to 1961; there are, for example, nearly 200 papers on the Colorado potato beetle quoted. Non-French sources are included equally with those in the French language, and there is no suggestion that many trivial French papers have been included unnecessarily. The bibliography should be very useful to research workers unfamiliar with any family of beetles.

We are becoming used to expensive books, but few will be prepared to pay some £22 for this, the first part of an eight volume treatise. It is difficult to think for whom it is designed. Although each section contains more information than can be found in any existing text-book of agricultural entomology, yet research workers will have to supplement this with much further reading. For example, some of the results of sampling soils for pests are given, but there is no room for any description of the techniques used. The bibliography, as I have said, is excellent, but this will be out of date in a few years. Nevertheless, reference libraries should contain this treatise, if they can afford the outlay.

K. Mellanby

NEW DEVELOPMENTS AT GLASGOW'S ROYAL COLLEGE

By Dr. S. C. CURRAN, F.R.S.
(Principal)

A RECENT Government announcement to the effect that the Royal College of Science and Technology, Glasgow, was to be the fifth University in Scotland was historical in several respects. Very obviously it marked the end of a long and frequently difficult passage towards full university status. Few people realize that the College was founded in 1796, and that it was the second of the major technical colleges in Europe, following the École Polytechnique (1794). From the start the Trustees attempted to create a college with the status of a university as this was indeed the expressed desire of the remarkable Prof. John Anderson, whose Will gave vent to his strongly critical views of some of the practices of the universities of his time, and his conviction that applied science was of very great importance indeed and worthy of university recognition. In fact the College was literally called Anderson's University from 1828 until 1877.

The history of development of the College proved eventful and was marked by many changes of fortune, yet over the years it progressively grew in importance and clearly filled a very real need in higher education. At one time it contained within itself a medical school (later Anderson College of Medicine) which nurtured the great Scottish medical missionary and explorer David Livingstone, and it contained likewise a College of Agriculture. Outstanding figures feature in its records, among them Birkbeck, Thomas Graham, Young, Reith, Baird and many others. A veritable host of distinguished Scots benefited from part-time studies at the College.

Perhaps less obviously the announcement represented one aspect of the coming of age of technology. In the case of engineering studies the extent of academic recognition has rather slowly yet steadily grown, but the applied sciences have proved more difficult to assimilate in the universities of this country. On the other hand, the Glasgow College had tended to narrow its scope until at the beginning of the century these subjects of engineering and technology were the only ones of real importance. The medical part of the College work was separated in 1886. The early years of this century were not the best in which to seek degree-awarding powers in technological centres, and in the light of this fact the affiliation of the College with the University of Glasgow in 1912 can be seen to be the beginning of a new period. From then onwards the College tended to devote its whole energies to work of degree-level and gradually passed more and more of its heavy load of responsibility for the more elementary work to other Institutions. Indeed, by 1919 it was in a position to receive direct financial support from the new University Grants Committee, a distinction which it shared only with the Manchester College of Science and Technology.

Thus the debt owed by the College to the University of Glasgow is a very real one. The interest of the University in the activities of the College was a constant spur to the College staff to emulate and if possible surpass the standards of those in the ancient and world-renowned University. However, the affiliation machinery by which degrees in a steadily increasing variety of subjects could be taken by students at the College proved increasingly unsuitable as a link between two major centres of learning, particularly when the academic staff of the College reached the hundreds. The new ideas born in the College were inevitably delayed in coming into operation by the more tortuous machinery involved so that some sense of frustration was engendered. More importantly the devotion of the College to technology was increasingly in harmony with the views of powerful minds such as those of Lord Cherwell, who firmly believed in technological universities. Indeed, by 1954 it was one of the three British technological Colleges singled out for special development and this increased the strength of the ambition to be a separate university.

Even so two main obstacles seemed to stand in the way of recognition of the College as a university with full university status and powers. First, there seemed to be a clash with the concept of a university as a multi-faculty institution; secondly, the College was geographically situated close to the ancient University of Glasgow. The first difficulty was more apparent than real. Many major technological colleges were anxious to introduce the study of the social sciences and subjects such as foreign languages normally within an arts faculty. Indeed some, such as the Massachusetts Institute of Technology, had made very substantial progress along these lines but most had not been permitted to follow their desire in this matter. It seemed, therefore, that if one was prepared to visualize a science-based university with faculties of science, technology and engineering and arts and social studies then this problem largely disappeared. In the second place, the rising level of demand for university places made it obvious that a populous region such as the Clyde Valley could well have two universities with great advantage. Indeed, the accepted principle of students going anywhere within Great Britain to the university of their choice made location a matter of the philosophy of the institution itself. The views held in the College were clearly in favour of a university that placed emphasis on science and technology and its existence within an industrial region and preferably right in the heart of a major city was particularly appropriate.

At the present time a modern university is well on the road to full development of its potentialities. The necessary physical space is available, and some 25 additional acres have been earmarked for the academic precinct of the new University, the main centre of which will be self-contained and extending over approximately 30 acres. The College playing fields are about to be extended, and in due course they will cover an area of 80 acres. They are sited about three miles from the College itself. Some outlying properties will be centralized, but the residential Chesters School of Industrial Administration (Management Studies) at Bearsden on the outskirts of the city will obviously continue to provide for special postgraduate instruction. At the moment the number of general student residential places is severely limited, but as soon as possible provision will be made for something like 1,000 places either within or very close to the precinct. In many other matters of student amenity a satisfactory position has been achieved. Thus the students entered a modern Students' Union Building in 1958 and the gymnasium is being extended to include a swimming pool.

Turning to the more basic matters, the College has always stressed the importance of staff teaching effort and with a very favourable staff/student ratio the interest of the students are safeguarded. The list of departments exceeds twenty, covering science, pure and applied, engineering and arts and social studies. The last of these contains six departments at present, these being: Econo-

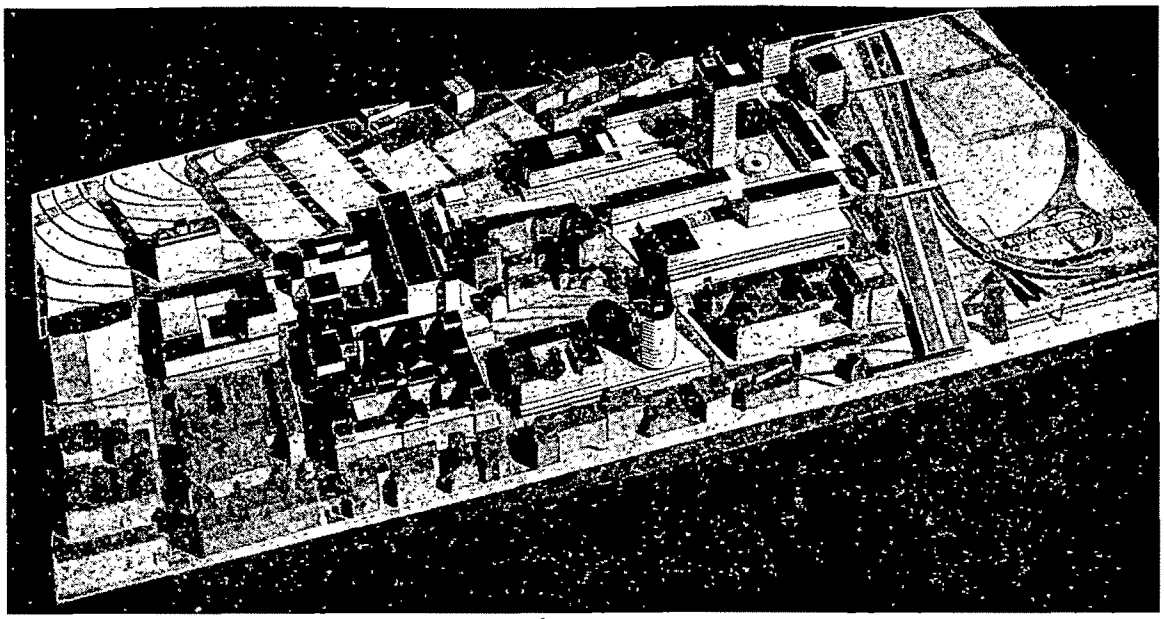

Fig. 1. Model of precinct of the new University

mics, Economic History, Political Theory and Institutions, Psychology, General Studies and Administration. The first students for degrees in these subjects or combinations of these subjects are being enrolled at present, and the first classes will begin in October of this year. The basis of admission will be the attestation of fitness of the Scottish Universities or the equivalent of the Northern Universities Entrance Board Matriculation requirements. With suitable advanced level qualifications a student can anticipate taking an honours degree in three years.

The ideas that led to the establishment of a Faculty of Arts and Social Studies may be explored as they illustrate clearly the probable method of academic development of the new University. By virtue of the nature of a Scottish Central Institution it was necessary for the College to confine itself largely within the bounds of science, particularly applied science and engineering. Thus in the later 'fifties the total number of departments was fifteen and some of these were very large. Among these large ones might be mentioned Mechanical Engineering, Civil Engineering, Chemistry and Pharmacy. Some in new applied sciences, such as Food Science and Microbiology, were in their earlier formative stages and growing, while among those of intermediate size were such departments as Textiles, Applied Physics, Applied Mathematics, Electrical Engineering and Chemical Engineering. Alongside these departments of science and engineering stood a strong department of Architecture, and this in some ways represented the nearest point of approach to the Arts. It was in the light of an obvious need to widen the horizons of the almost exclusively vocational education of the students that a strong postgraduate and residential centre was first created in 1954 and this was later centred at Chesters. This centre has been primarily concerned with the subject of industrial administration, but in catering for a residential study body of nearly 60 it engaged in a rather extensive range of tasks, collaborating with members of staff of the Engineering departments particularly well so that the students in those departments learned a good deal about Industrial Economics and a variety of other subjects, some closely relevant and others loosely linked to their main studies. The same department organized within itself a sub-department, known as General Studies, and this sub-department now stands as a department in its own right. The staff have many disciplines at their command including, for example, English, history and geography. They included within their responsibilities a number of special tasks such as the teaching of history of science, contributing to special postgraduate courses such as environmental engineering, while fulfilling their main task of stimulating the interest of almost all College students in the achievements of Western civilization. These courses seemed to be welcomed for their own sake by the great majority of students. The lesson drawn from these ventures and indeed from the well-established principles of sound education was that a much greater effort should be made to introduce social studies and arts for their own sake. Only thus could it be expected that really first-class teachers and research workers in those fields could continue to be recruited to the staff in adequate numbers.

A substantial start is now about to be made and in the first instance the new departments will be: Economics, Economic History, Political Theory and Institutions, Psychology and, as already noted, General Studies and Administration (complementing the postgraduate Industrial Administration). It is expected that the number of departments will grow until very strong Schools of Social Studies and of Arts will be functioning alongside the strong and vigorous Schools of Science and of Engineering.

The method of growth is a completely logical one. It can, in fact, be regarded as an extension of the province

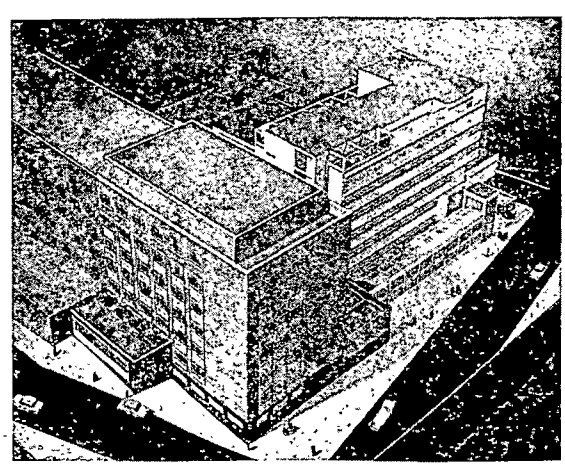

Fig. 2. Extensions to Mechanical and Engineering Departments in Cathedral Street

of science, using that word in its broadest sense. Obviously it will be desirable that the approach to the social sciences, and if possible the arts, will be such as to inject into their method as much as possible of the scientific techniques and method. With some of the subjects such as economics and psychology it is obvious that this can be done, and econometrics, for example, will feature strongly. Clearly many of the subjects can benefit from a maximization of the use of mathematics, particularly such branches as statistics. The massive application of computer techniques obviously can open up fresh horizons in some of the social sciences. The same desire to innovate can be seen in the construction of a television studio in the new social science building due to open this month. The whole subject of communication is changing at present at a very great rate indeed, and it would seem most desirable that a new university claiming a real concern for the sciences should be prepared to experiment in its approach to some of the more traditional branches of learning. The complementarity of the arts and sciences must be stressed and the integrating forces revealing the unity of knowledge and understanding given full play. This can prove to be one answer to the problem of the so-called two cultures.

Students are at present being enrolled for a range of degree courses in social studies and a handsome new building which can accommodate at least 400 students and 50 members of staff will shortly be completed. It is probable that the new university will have 2,900 students by the end of the present quinquennium in 1967, and it aims to have approximately 4,000 by the early 1970's. The number of postgraduate students, at present about 10 per cent of the total, will rise steeply with the increasing need for such degrees as M.Sc., and later some 25 per cent of the students may well be doing postgraduate work.

It is a time of great expansion, indeed, almost a time of revolution in the universities. The College joins the new universities, and although it has a long history behind it there is no question of the freshness of its spirit and enthusiasm. It is determined to play a full part in the adventure of making fresh approaches to higher education. Starting with technology firmly established, it will in some ways be in a unique position, able to develop in a fashion not unlike that discussed by Sir Eric Ashby[1].

There is obviously a very great need for more university places, though at this moment it can be questioned if the need is proportionally so great in Scotland. Most authorities agree that the demand for places in technology is not increasing at as high a rate as in other fields, particularly in arts. It is to be hoped that a new view of the technologies, different from the somewhat unfortunate one deduced from the recent study, *Technology and the Sixth Form Boy*[2], will be observed soon. As to the overall size of the Scottish demand for places many believe that the ordinary and advanced grade certificates will prove in due course very stimulating and lead to a rapid increase in the number of those ambitious to go on to University. In the meantime there may be increased opportunity for those English students who believe in the value of the education that the new University is able to offer. Many students come from overseas to the College, indeed, rather more than 15 per cent of the students come from more than 30 countries, but a relatively small fraction comes from England. This may be due to the erroneous picture of Glasgow and its environs held by many.

All concerned are determined to succeed in their new tasks. The College has prospered for sixty years as a senior central institution under the wise dispensation of the Scottish Education Department and as a College affiliated to the University of Glasgow for the past fifty years and benefiting from the care of the University Grants Committee. As it transforms to the first university founded in Scotland in nearly five hundred years, it is conscious of its responsibility and exciting opportunity.

REGULATION OF GROWTH IN SIZE IN MAMMALS

By Dr. J. M. TANNER*

Department of Growth and Development, Institute of Child Health, Hospital for Sick Children, University of London

ALMOST striking characteristic of the growth of mammals is that it is self-stabilizing, or, to take another analogy, 'target seeking'. Children, no less than rockets, have their trajectories, governed by the control systems of their genetical constitution and powered by energy absorbed from the natural environment. Deflect the child from its natural growth trajectory by acute malnutrition or a sudden lack of a hormone, and a restoring force develops so that as soon as the missing food or hormone is supplied again the child catches up towards its original curve. When it get there it slows down to adjust its path on to the old trajectory once more.

This article is concerned with the problem of how the child 'knows' that it has reached its old trajectory and should slow down. More generally, it elaborates a hypothesis as to how growth in size is regulated in mammals, and seeks to explain the mechanism by which velocity of growth is rapid in early childhood and becomes progressively less. I am frankly speculative but the hypothesis is presented for test, since one of the reasons for the relative neglect of experimental work on growth seems to be the lack of appropriate models.

* Substance of a portion of the first Harold E. Jones Memorial Lecture of the Society for the Study of Child Development, delivered at the University of California, Berkeley, April 1963.

In normal circumstances, the growth of a healthy well-nourished child is very regular. The upper section of Fig. 1 shows the measurements of height of a boy in the Harpenden Growth Study taken every six months from age 4–10 years by a single observer, Mr. R. H. Whitehouse. The circles represent the measurements, and the solid line is a simple mathematical curve of the form $h = a + bt + c \log t$ (where h is height and t age) fitted to them. None of the measurements deviates more than 4 mm from this line, although the experimental error of measuring height may be 3 mm even in experienced hands. The lower section of Fig. 1 shows the same data plotted as six-monthly velocities; the continuous curve is the first derivative of the fitted curve in the upper section. At adolescence a different curve is needed, but the Gompertz function, which is a sigmoid with four parameters, fits just as well at that time as the simple curve does earlier.

When a child or young animal is starved, however, growth slows down, and when it is fed adequately once again a 'catch-up' period occurs during which it grows at (in the human case) up to four times its natural velocity for its age. Fig. 2 illustrates the effect on height (or length) growth of two periods in which a young child's food intake was much reduced for psychological reasons. Above is the curve of body-length at successive ages ('distance' curve)

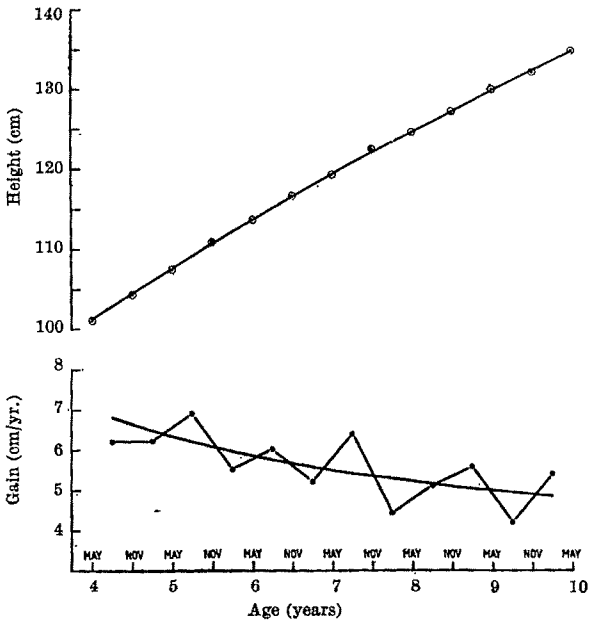

Fig. 1. Growth of a boy in the Harpenden Growth Study measured every six months by R. H. Whitehouse
Above, 'distance' plot of height achieved at each age; below, velocity plot of average velocities each six months. Solid lines: above, curve of form height = $a + bt + c \log t$ (t = age) fitted to individual's height-achieved points; below, the derivative of the fitted curve (from Tanner, ref. 10)

and below the average rates of growth at successive periods plotted against the 50th percentile lines for length-growth velocity (for details see Prader *et al.*[1]). The catch-up is apparently complete in that the child is quite normal in both length and velocity of length growth by age 5.

Two further examples are given in Figs. 3 and 4. Fig. 3 represents the growth of a girl with an adrenal tumour which secreted excessive quantities of cortisol, a growth-retarding substance (Cushing's syndrome). At the age of four the tumour was removed. The catch-up was initially very rapid, and steadily decreased in velocity. By the time she was eleven years old this girl had only reached the 20th percentile for height, so perhaps the regulatory forces had been insufficient to make good the effects of the long period of deflexion from her natural trajectory.

Fig. 4 concerns a boy who was hypothyroid from his seventh year or before up to the age of twelve years, when thyroid administration was begun. In early childhood height velocity had been average, but from seven to ten years it dropped and from ten to twelve actually became zero. During the first eight months after thyroid hormone was given the height-velocity reached more than twice average for chronological age. The boy's growth soon moved back to the normal pattern and he underwent an adolescent growth spurt which was average in intensity and occurred at the nearly average skeletal age of fourteen years. His chronological age was nearer sixteen, however. It seems that some of the years of hypothyroid arrest had been eliminated from his biological calendar, so that he was still two years behind; but by the age of twenty when his skeletal maturation was practically complete he had caught up presumably completely in height.

In all these examples, the catch-up is at first rapid and then decreases, the catch-up velocity curve resembling a telescoped version of the general mammalian growth-curve. Before setting up a hypothesis to explain this we should note that during a typical catch-up the whole organism grows rapidly and in at least approximately a proportionate manner. It is difficult (though not impossible) to see how this could happen unless the stimulus to catch up is a systemic one circulating with the blood to all parts of the body. In everything that follows it must be remembered that we are dealing with growth in size and not in shape. So far as the present results go, shape in the human being is little affected by a slow-down and subsequent catch-up of growth. Differential effects of malnutrition on limbs and trunk, for example, have never been proved to occur, though they have been suggested by analogy with some results on cattle. Growth in shape must clearly be regulated by peripheral mechanisms rather than the central mechanism for size postulated here.

We do not know what the catch-up stimulus is; suffice it to say here that it seems likely to be a balance of several hormones, released or co-ordinated by the pituitary. The factor or factors must be released in response to a signal, and it seems to me that the characteristics of catch-up require this signal to represent the degree of mis-match between the actual size of the organism and the size required at that age by the hypothetical built-in or 'target' growth curve. As the target curve is approached the mis-match diminishes and the catch-up slows down. For the mis-match to be read, both actual size and 'target' size must somehow be represented in the organism. At

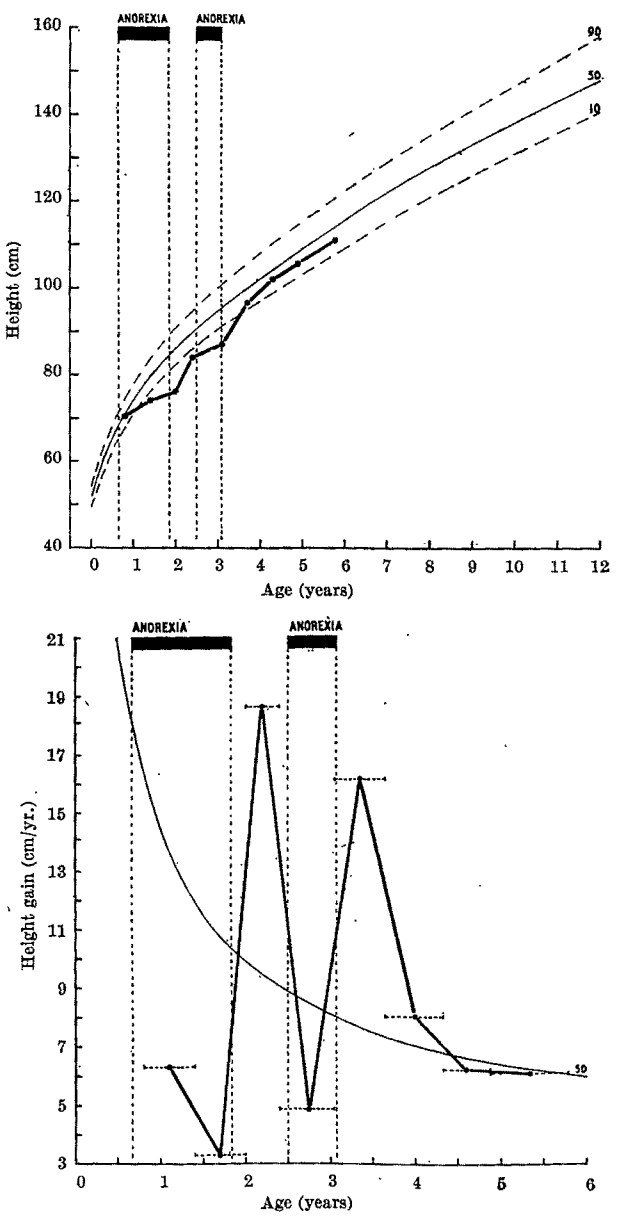

Fig. 2. Two periods of catch-up growth following episodes of anorexia nervosa in a young child (from Prader, Tanner and von Harnack, ref. 1)

present we do not know how either representation is made. It is possible that the mis-match is a peripheral phenomenon, and occurs in all cells in all tissues, the cells themselves each carrying the code for their own maturity. The catch-up in treated hypothyroidism might indeed be explicable on this basis. But it seems an unlikely hypothesis for explaining most catch-ups, and for explaining the normal control of growth in size, which is our ultimate objective.

Consider 'target' size. Suppose that somewhere in the brain a tally is kept of the time passed since conception, or rather since the age, perhaps about three months after conception, when the mechanism of the tally begins to function. This tally can represent the target curve, for both are fundamentally series of signals made against a continuing time-base. Suppose, purely for the sake of simplicity, that the tally consists of a steady increase in the amount of a substance in certain nerve cells, then the form of the growth-curve may be represented at any time by (some function of) the concentration of this substance (Fig. 5).

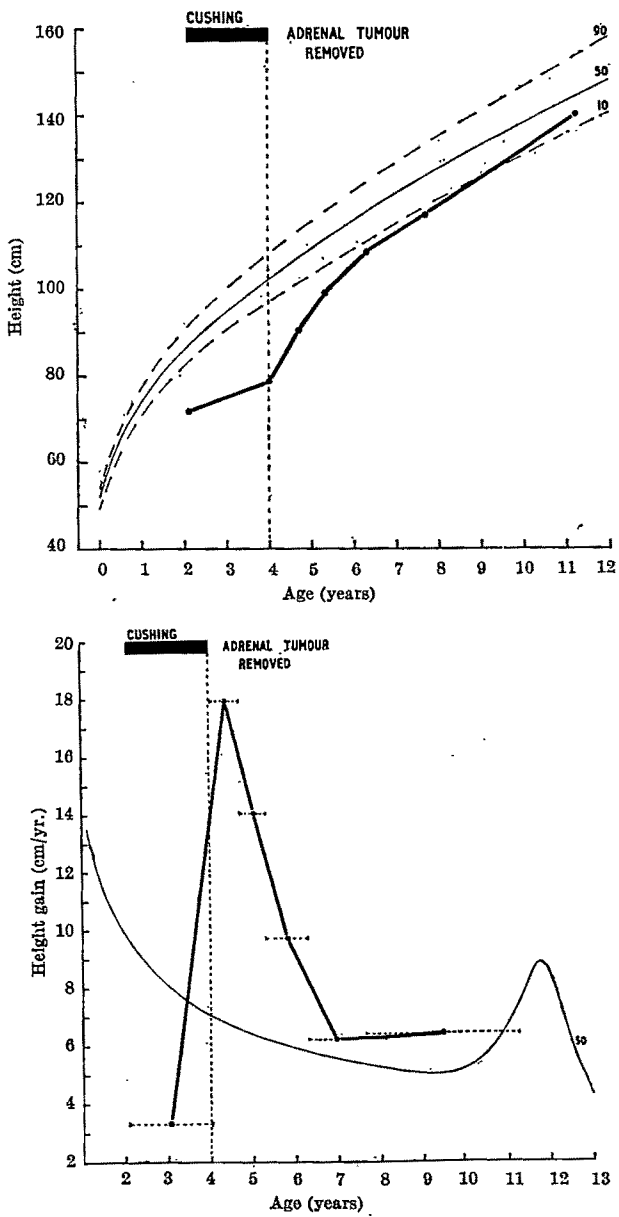

Fig. 3. Girl with Cushing's syndrome showing catch-up after removal of adrenal tumour at age 4 (from Prader, Tanner and von Harnack, ref. 1)

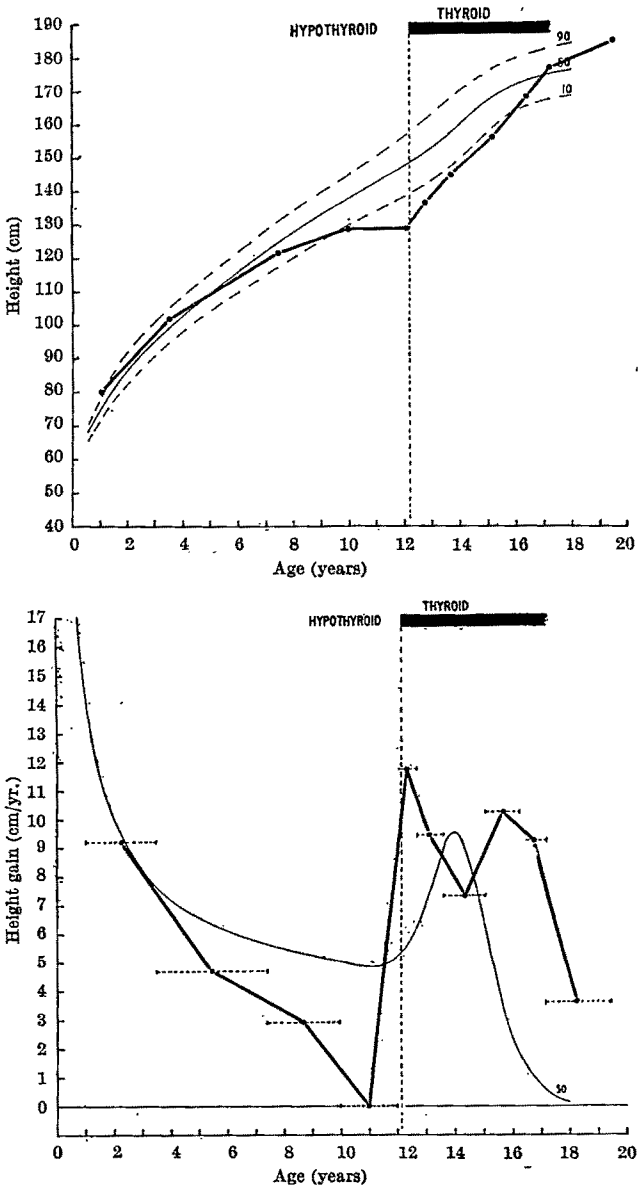

Fig. 4. Catch-up in a hypothyroid boy following treatment at 12 years old (from Prader, Tanner and von Harnack, ref. 1)

Now as to actual size: it is scarcely conceivable that the body can represent its actual extension in space. Suppose instead that the organism measures its actual height or size by the concentration of some form of circulating substance produced by cells as an inevitable accompaniment to the process of growth or protein synthesis. In this supposition I follow the most provocative and stimulating ideas of Paul Weiss[2], except that he envisages these substances—which he calls anti-templates—as numerous and tissue-specific and acting directly on peripheral cells, whereas I prefer to think primarily of a single substance acting at the brain-level. In the simplest model then, the concentration of this substance (which we will call 'inhibitor') would be proportional to the size of the organism. Its actual concentration can be measured against the concentration expected on the basis of the time tally and the discrepancy used as the mis-match signal for release of growth-stimulating factor. If also for the sake of simplicity we suppose that the time tally consists of a steady increase in the number of receptive sites for growth-inhibitor substance, then the mis-match signal would consist of the number of unoccupied sites.

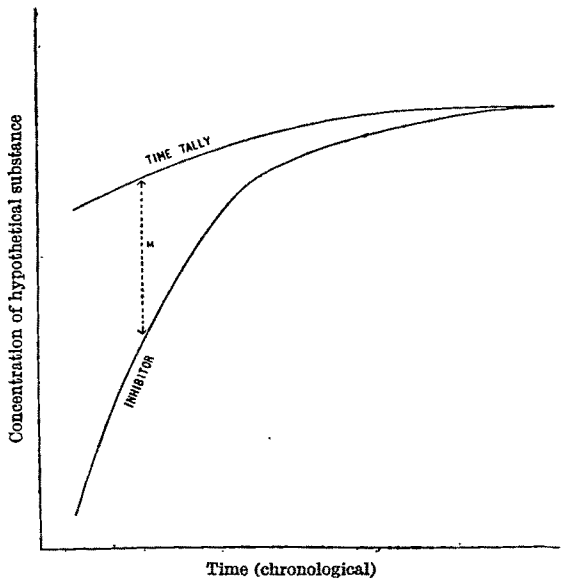

Fig. 5. Hypothetical relations underlying supposed growth-controlling agents. The quantity m represents the mis-match signal

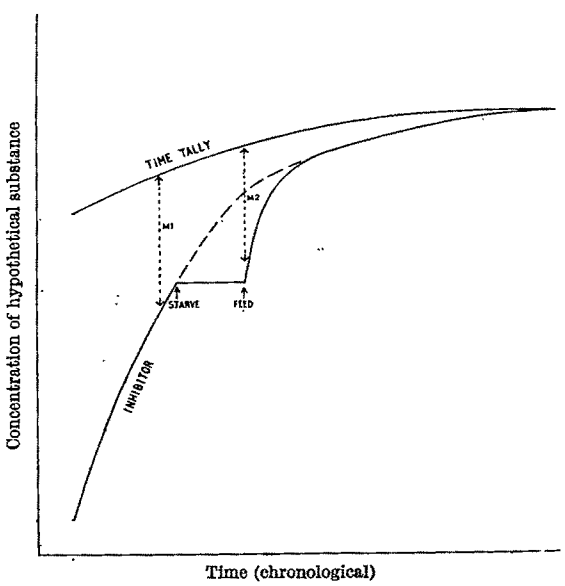

Fig. 6. Velocity expected in catch-up growth, assuming control system of Fig. 5. Catch-up velocity is proportional to the mis-match m_2, which is greater than the mis-match when starvation began, and equal to mis-match at an earlier age, as represented by $m_1 = m_2$

The tally need not, of course, represent clock time; on the contrary, it will represent the maturation rate for each individual organism. The rate of tally, and rate of change of that rate, will be an individual, presumably inherited, characteristic.

The growth inhibitors are purely hypothetical substances. Neither their origin nor their site of action is known. Weiss supposes that each type of tissue produces inhibitors as it grows, and these diffuse out into the blood and inhibit the growth of the same tissue elsewhere in the body by local action at the cellular level. This is doubtless a valid model for lower animals. It may also be valid for certain aspects of shape in mammals. One might even suppose at least *a priori*, that the general correspondence of development throughout the whole body of a given individual of a tissue such as muscle or bone[3] might be brought about in this way. But in the control of mammalian growth, certainly in size and probably even in bone and muscle, it seems more likely that the inhibitors act centrally. Furthermore, it seems unlikely that many tissues produce tissue-specific inhibitors (though kidney and liver may). Clearly the limbs contribute nothing important, for children with poliomyelitis, or even entirely missing limbs, grow perfectly normally in the rest of their body: they do not hypertrophy due to lack of inhibitors. Thus bone muscle and fat seem not to be the source of inhibitor production. The liver is the obvious choice; but it is very difficult to provide evidence for this, since damage to the liver diminishes the ability to metabolize substances essential for growth and hence may result in a slowing-down of growth even if inhibitor production is also diminished.

We may reasonably think that the same mechanism underlies the form of the normal velocity curve of growth, wherein a baby grows faster than a nine-year-old child. Suppose, again for simplicity, that the tally accumulates at a constantly decreasing rate as illustrated in Fig. 5. Suppose also that the inhibitors occur in proportion to the synthesis of protein in the cells, that for each amino-acid assembled into protein a molecule of inhibitor is produced. Then the inhibitor concentration would rise fast at first and slowly later. The mis-match (m) between these two concentrations would be large at first and decrease after the manner of the growth velocity curve. In this simple model the concentration of growth-stimulating factor is directly proportional to the mis-match and the velocity of catch-up is supposed to be directly proportional to the concentration of growth-stimulating factor. (Really one or other of these relationships might well be logarithmic.)

As Fig. 6 shows, the model represents the chief feature of catch-up correctly. The catch-up velocity seems usually to be not only greater than the velocity expected at the age of catch-up, but also greater than the velocity expected at the age at which growth stopped[1]. The model predicts that the mis-match and hence the catch-up velocity will be the velocity appropriate to a younger age than this, how much younger depending on the relative curvatures of the time-tally and inhibitor lines. The model also predicts that catch-up growth, following a given time of growth arrest, will be more intense at young ages than at older ones. This is generally thought to be the case, although my own results give no direct evidence for it.

I should not press such a crude model too far; but one cannot help noticing that the relation between the time-tally curve and the inhibitor curve resembles that between the growth of the central nervous system and the growth of the rest of the body[3]. Perhaps one of the reasons that

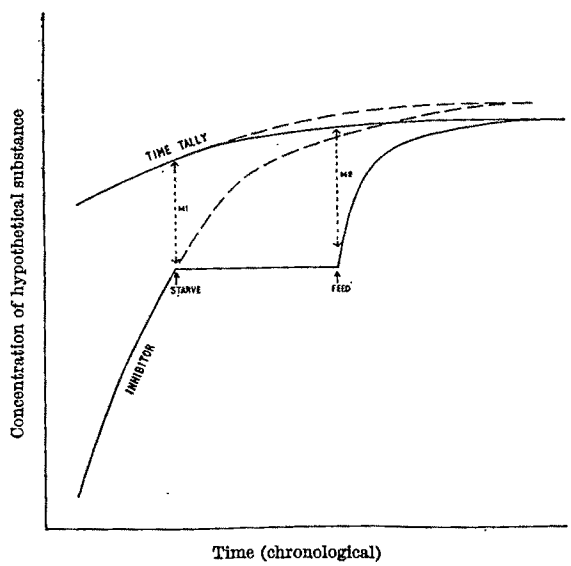

Fig. 7. Hypothetical explanation of incomplete catch-up following prolonged starvation. Time-tally velocity is supposed to be reduced irreversibly under these conditions

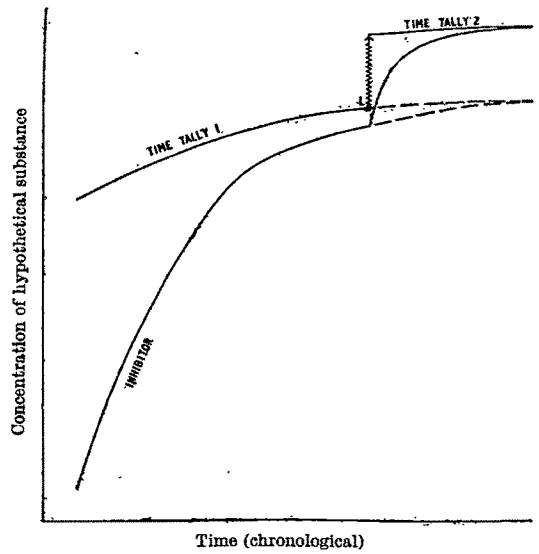

Fig. 8. Hypothetical linkage of two systems. Switch to new system occurs at L, a point supposed governed by velocity or integral of time tally

the central nervous system develops ahead of the remainder of most of the body is that the time-tally is located there. It would be logical if the earliest developing part of the organism carried the programme for the growth of the remainder.

Of course, this model may be quite wrong, and if not quite wrong, is certainly very much over-simplified. The true situation is without doubt more complex. For example, I have assumed that the tally continues unaltered even in circumstances which stop the rest of the organism growing altogether. This is somewhat unrealistic. Catch-up is probably incomplete if the period of growth arrest by starvation, say, is prolonged. To explain this we may assume that the time-tally is somewhat affected by the starvation though to a much lesser extent than the rest of the body. It may fail to resume its old rate at re-feeding (Fig. 7) or it may return to its old rate but without a catch-up. Alternatively we can assume that catch-up depends not only on mis-match but also on the velocity of time-tally (or its integral or total amount).

I have so far ignored the existence of the adolescent spurt and dealt with growth as though it gradually ceased at the end of its exponential pre-adolescent curve, as it does in fishes and reptiles. In primates particularly there is a secondary growth system superimposed on this basic one, causing a new increase of growth rate to occur just when the impetus of the basic system is nearing its end. This secondary system, be it noted, is not a necessary condition for growth to cease, even in man. Children who suffer gonadal or gonadotrophic failure at adolescence may not close their epiphyses, but their growth gradually ceases all the same (see, for example, cases *C* X and *C* XII of Bayer and Bayley[4]). Rats never close their epiphyses and reptiles do not have epiphyses to close. Evidently, it is the dwindling of the mis-match signal which causes growth to slow down; finally, the signal becomes vanishingly small, and the organism remains in a steady state of equilibrium. There is no reason to suppose that the adolescent growth cycle is organized in a different manner from the basic cycle, but it uses different substances. Its time-tally and its inhibitors must be distinct from those of the basic cycle, just as its growth-stimulating factor is also distinct. But it is also linked to the basic cycle in that its beginning occurs when the basic cycle has reached a certain point in its evolution.

Linkages such as these occur between many systems during growth. The simplest way in which the linkage could occur is illustrated in Fig. 8.

Here it is supposed that when the threshold point L on the time-tally is reached a new tally is activated and the switch made. L might be specified either by the velocity or the integral or accumulated amount of the time tally. We could explain early and late maturing by variation in the place of L on the curve. We could account also for the fact those who mature early have a greater adolescent spurt velocity than those who mature later; since when L is placed nearer the origin of the curve the total mis-match will be greater than when it is placed far from the origin.

But this simple linkage alone does not seem able to account for the postponement of puberty after starvation. Though the facts here may be a little questionable, it seems that if a period of starvation occurs at the normal time of puberty, puberty is delayed, and that on re-feeding puberty does not occur at once (as demanded by the simple linkage model), but only after a certain amount of catch-up growth has occurred. We could account for this by assuming that the switch mechanism is dependent not only on the velocity of the tally reaching a critical value

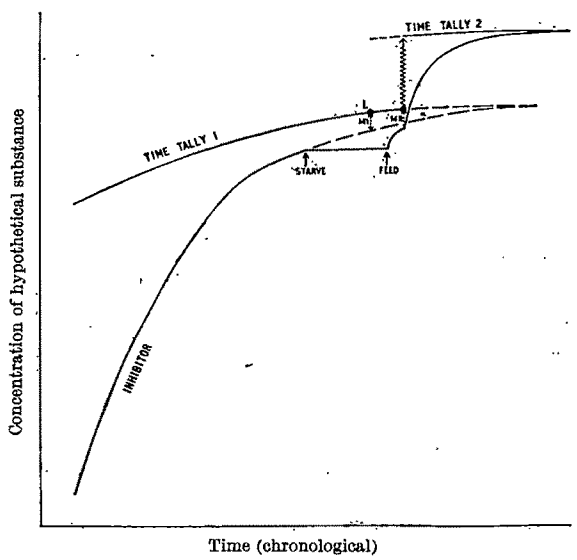

Fig. 9. Hypothetical linkage of two systems under conditions of temporary starvation. The distances marked m_1 and m_2 are supposed equal

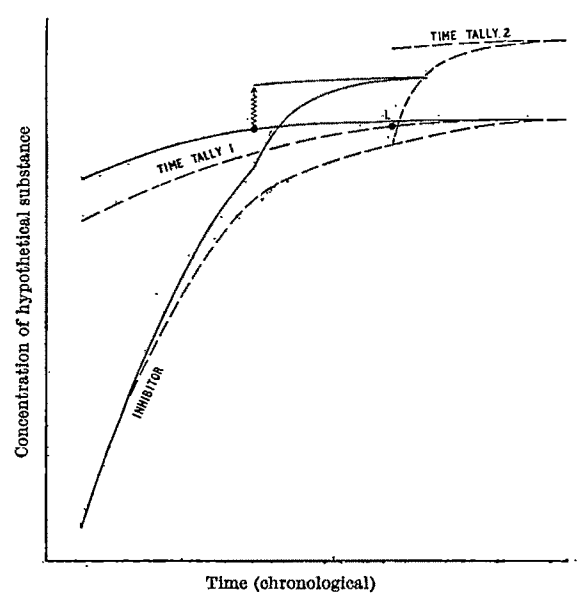

Fig. 10. Hypothetical curves for precocious puberty, assuming shape of time-tally changes, and point of switch L still occurs at usual velocity on tally. Dashed lines, normal child; solid lines, precocious puberty

L, but also on the mis-match reaching a certain value m_1 (Fig. 9). In this case ordinary catch-up would occur until the mis-match reached m_2, equal to m_1. As the scanty experimental and clinical data make it seem probable that in fact puberty occurs before the catch-up velocity has actually fallen the whole way to the usual pre-adolescent velocity, we may think that the relationships are quantitative, and that a further lowering of the tally velocity after L is passed makes possible a higher mis-match, the combination of the two being the quantity required to reach a threshold value. A two-factor linkage such as this seems more typical of events in growth than a single-factor one, in that it permits greater variability among a number of individuals. In this sense it is a 'looser' coupling. Actually the recent results of McCance[5] on starvation and re-feeding in pigs agrees with a fairly simple direct linkage; for puberty occurred in the starved and then fed pigs much before the body has caught up to its usual puberty size.

The model must be capable of explaining the disorder of precocious puberty. In some cases pubertal changes occur early, at a nearly normal size for chronological age; the children then finish their growth as very small adults. Essentially the same can be brought about in rats by destruction of an area in the hypothalamus; in an experiment of Donovan and Werff ten Bosch[6] vaginal opening occurred at 33 days instead of 40, but the growth in size of body was not accelerated. In this case, we may suppose that L has been drastically moved back along the tally curve, that is, that the linkage occurs at a higher tally velocity than normal. Physiologically, it may be that the inhibitory impulses to the pituitary are steadily diminishing as the velocity of the time tally diminishes (that is, as the maturity of the cells increases). If some of the inhibitory cells are destroyed, then the total effective inhibition diminishes, and the threshold is reached at an earlier point on the tally curve.

Other cases occur in which the child grows excessively fast from an early age, at first without any signs of puberty. He reaches puberty early, however—very early as regards chronological age and somewhat early as regards size. The growth regulation of such a child is represented in Fig. 10. The simplest supposition is that the form of the tally curve is distorted so that its velocity is at first abnormally large. This would give rise to an abnormally large mis-match at the beginning of growth and hence to the accelerated growth. The point L would occur early in chronological time, if it reflects the same critical velocity as usual in the time tally. In this form of precocious puberty therefore, puberty would occur early without any shift in time-tally threshold.

A striking example of experimentally produced disturbance of the regulatory mechanism has been given by the work of Kennedy, McCance and Widdowson in rats[7,8]. Rats which are malnourished during the first 21 days following birth—which corresponds very approximately to the period from the fourth month of fœtal life onwards in man—never catch up afterwards on their well-nourished litter-mates' curve, although they do show some catch-up growth on unrestricted feeding. When rats are starved at older ages catch-up does occur. In terms of the hypothesis presented here, the malnutrition occurring while the brain was still relatively rapidly growing apparently resulted in permanent damage to the time-tally mechanism. The hypothalamus seems the most likely location of the mechanism, particularly in view of the work of Harris and Jacobsohn[9], who showed that a new-born pituitary grafted into an adult hypophysectomized rat functioned as an adult pituitary as soon as vascular connexions were established. Thus information as to maturity is carried in the hypothalamus, or at some higher point in the brain.

IN THE SERVICE OF SCIENCE, INFORMATION AND THE ENJOYMENT OF LEISURE

THE Lord Mayor of Oxford, in opening the Robert Maxwell Bookshop at Oxford housed in the Magdalen College Waynflete Building, described it as a bold enterprise and a most imaginative venture.

This new and most remarkably designed bookshop is also a cultural and information centre. Its 10,000 sq. ft. of space holds seven separate shops: including a general bookshop; a scientific, technical and medical bookshop; a paperback bookshop; a record and music shop; and finally, a stationery, office equipment and systems shop. In addition, there is an area designed for lectures, exhibitions and live recitals.

Service—not only to the people of Oxford but also to visitors in general—is the keynote of Maxwell's seven bookshops in one, planned carefully for more than three years. Its design and facilities incorporate the most modern American, British and Scandinavian techniques of displaying, recording and disseminating information of the printed and recorded word.

Students in Britain, elsewhere in the Commonwealth, and most other countries of the world will have the benefit of a new service in the supply of modern text-books, enabling them to acquire, under the Maxwell Budget Plan, all the books and other educational aids they need at the beginning of their full- or part-time studies and to pay for them by easy monthly instalments.

A unique, free bibliographical service for research workers and managers will help scientific research, industry and commerce to keep up to date with the latest professional publications throughout the world. Maxwell's free bibliographical service, based on co-operation with more than 1,000 of the most important publishers and institutions at home and abroad, brings users—on individual I.C.T. punch cards—accurate weekly advance information about all significant new publications on subjects of their own choice. The service is available in 435 subject classifications, ranging from medicine to packaging and marketing, to high-energy physics, plastics, building materials and teaching techniques.

A unique new feature of Maxwell's is the information systems, office equipment and stationery department. This will provide expert advice through its information and office-efficiency specialists—in consultation with each individual firm—on the best procedures, forms, facilities and equipment to be used to ensure the improvement or establishment of efficient and effective low-priced information systems, libraries and office methods in their firms.

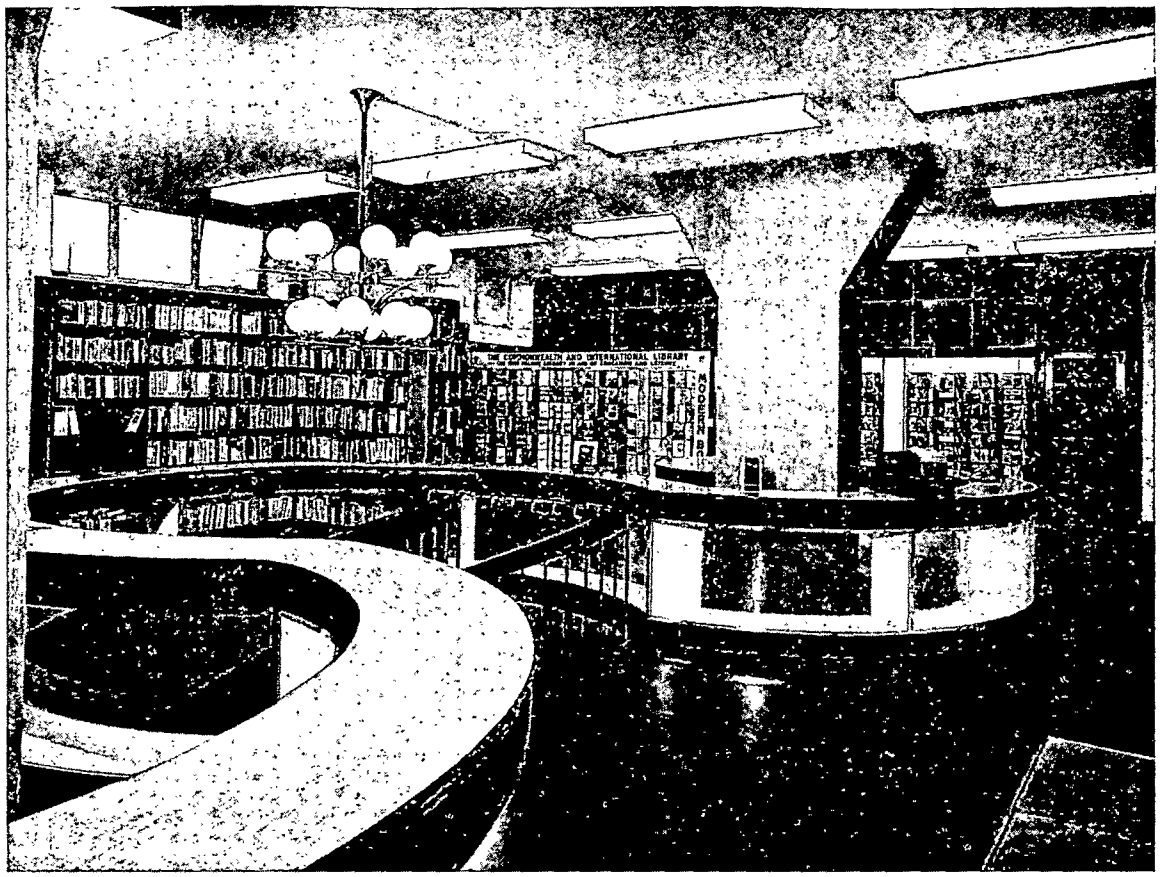

Fig. 1. Showcase and paperback book and journal section of the Maxwell bookshop in Magdalen College, Oxford

A further facility of interest to scientists is the stocking of a substantial range of scientific and medical books in German, French and Russian. There is also a 'teachers and librarians only' room; in this room are displayed the latest text-books and teaching aids.

Response from visitors from overseas suggests that Maxwell's will become the prototype of a chain of 'twentieth-century bookshops for university towns' all over the world. Following his recent tour of Maxwell's, for example, Dr. J. A. Matheson, vice-chancellor of the rapidly expanding Monash University, Victoria, Australia, invited Maxwell's to establish a bookshop on the University grounds at Clayton. A professor interested in plans for new buildings at Grenoble University has invited Maxwell's to participate. Long before these developments come to fruition, however, a second Maxwell's will be in operation in September opposite the University Medical School in Edinburgh.

OBITUARIES

Prof. Sidney Russ, C.B.E.

Sidney Russ was born in London on December 2, 1879, and died on July 27, 1963. He started his career as a physicist in London, graduating from University College in 1905, after which he went to Manchester as demonstrator in physics. Here he spent five years in the exciting atmosphere of Rutherford's laboratories when new discoveries in radioactivity were almost a weekly occurrence. From this came his life-long interest in radioactivity, which led in 1910 to a most unusual step for a physicist to take. Having been awarded a Beit Memorial Fellowship, he decided to take it up in the new Cancer Research Laboratories of the Middlesex Hospital. This was followed in 1913 by his appointment as physicist to the Hospital, almost certainly the first appointment of its kind in the world and perhaps the starting point of a new branch of applied physics. In 1919 Russ transferred from Hospital to Medical School, and in 1920 was appointed to the newly instituted Joel chair of physics, which he held until his retirement in 1946.

During his early years at the Middlesex Hospital, Russ pioneered vigorously the application of precise physical principles and techniques to the use of radium and X-rays in medicine, a task for which his Manchester years well fitted him. Later his interests turned more to the biological and biophysical aspects of ionizing radiations, his greatest contribution probably lying in the field of radiation protection. His work with Gladys Scott on the biological effects of X- and gamma-rays at low dose-levels, which seemed rather naïve and crude at the time, was clearly pointing the way to the enormous range of investigations in this field carried out in recent years.

In 1919 there was growing concern about the hazards of the uncontrolled use of ionizing radiations. Russ became the first secretary of the British X-ray and Radium Protection Committee, the first recommendations of which were published in 1920. This slim document, produced before there was even an accepted unit of radiation dose, was quickly recognized throughout the world and became the pattern for future codes of practice. In its style it clearly shows the imprint of the hand of Russ.

Russ was scientific secretary of the National Radium Commission, secretary of the Medical Research Council Radiology Committee, president of the Röentgen Society, active in the affairs of the King Edward's Hospital Fund and the British Empire Cancer Campaign, and was awarded a C.B.E. in 1931.

Large numbers of doctors will remember Sidney Russ as a teacher of both undergraduate medical students and radiologists. In many parts of the world, I have met ex-students who remember his concise, slightly pedantic lectures and his firm, but always kindly, demeanour in the examination room or laboratory. In the laboratory he was a hard taskmaster, given to flights of fancy but always firmly down to earth when results were produced. Many a humble research worker, both medical and non-medical, struggling in the borderline field between physics and biology, has good reason to remember his kindly help and understanding.

The passing of Sidney Russ breaks one of the few remaining links with those exciting days when the new science of atomic physics invaded and revolutionized a major branch of the art of medicine.

J. E. Roberts

Prof. G. M. Petropoulos

Prof. George M. Petropoulos, director of the Laboratories of Electrical Measurements and High Voltage Engineering of the Technical University of Athens, died suddenly in Oslo on June 24 at the age of fifty-four. He had been attending a meeting of Committee No. 8 (Lightning and Surge Phenomena) of the Conférence Internationale des Grands Réseaux Électriques in Trondheim and was on his way back to Athens when he suffered a heart attack and died in his hotel.

After graduating in the Technical University of Athens in 1931, George Petropoulos joined the Piraeus Electricity Company and in 1937 went to the Technical University of Berlin for two years, where he began his researches on high-voltage phenomena for which he was so well known. He returned to the Piraeus Company for a few years and was appointed reader in 1946 and later professor in the Technical University, during which time he also acted as adviser to the Public Power Corporation. His main scientific contributions have been on transient electrical phenomena on transmission line systems, and on breakdown of air in uniform and diverging electrical fields, and it was on work on this latter subject that he was reporting in Trondheim. He had developed a vigorous research school in Athens and had become an authority on electrical discharges in gases.

His colleagues from many countries represented on the Conférence Internationale des Grands Réseaux Électriques will remember his quiet penetrating analysis of problems studied in committee, and his wise counsel will be greatly missed. He visited Britain many times, and was attracted to the English way of life; British scientists were always made very welcome when visiting him in Athens. He leaves a widow, one son and a daughter.

T. E. Allibone

NEWS and VIEWS

Pure Mathematics at Leeds: Prof. A. W. Goldie

Mr. A. W. Goldie, reader in algebra in King's College (University of Durham), Newcastle upon Tyne (renamed the University of Newcastle upon Tyne as from August 1) has been appointed to the newly established second chair of pure mathematics at the University of Leeds. Mr. Goldie took Part II of the Mathematical Tripos at Cambridge in 1941, and then spent the rest of the war years in the Armament Research Department, Ministry of Supply. After two years as an assistant lecturer in the University of Nottingham, he was appointed in 1948 to a lectureship at Newcastle, where he was promoted to senior lecturer in 1959 and to reader in 1960. During the academic year 1960–61 he was a visiting research associate at Yale University. Apart from an excursion into functional analysis with two joint papers on Banach algebras, his research work has been entirely in algebra, with the theory of rings as his main field. A group of papers on non-commutative rings with maximum condition were of special importance and have aroused widespread interest. The break-through with which this work began was a complete structure theory for prime rings with maximum condition.

U.S. National Bureau of Standards; New Appointments

Dr. R. D. Huntoon, at present deputy director, has been made responsible for managing the Standard Reference Data Program as deputy director for basic standards and services. Dr. Huntoon will continue to manage the Bureau's programmes associated with the development of basic measurement standards and for calibration services associated with the dissemination of the basic measurement standards. Dr. I. C. Schoonover, at present associate director, has been appointed to the newly created position of deputy director for technological standards and services. He will be responsible for all programmes involving the development of industrial standards and test methods, which provide a common basis for the exchange of technological products and services in industry and commerce. Associated with these changes, the Commodity Standards Division of the Office of Technical Services, U.S. Department of Commerce, has been transferred to the National Bureau of Standards to become part of the Bureau's increased and concentrated effort on technological standards. Dr. A. T. McPherson, formerly an associate director of the Bureau, and more recently associate director of the Office of Technical Services, is returning to the Bureau as special assistant to the director for international standards. R. B. Scott, at present acting director of the Bureau's Boulder Laboratories (Colorado), is appointed to the new position of manager of the Boulder Laboratories.

Dr. R. D. Huntoon

Dr. Robert D. Huntoon has been a deputy director of the National Bureau of Standards for the past five years. For more than twenty years he has organized and directed fundamental research at the Bureau on atomic physics, electronic digital computers, electron physics, electronic instrumentation, and electronic ordnance devices, including guided missiles. Dr. Huntoon has been the recipient of many awards, including the Presidential Certificate of Merit and Department of Commerce Exceptional Service Award for his work on V. T. fuses, the Washington Academy of Sciences Award in Physical Sciences, etc. He joined the Bureau staff in 1941, and played an important part in the development of V. T. fuses. From 1944 until 1946, Dr. Huntoon acted as consultant to the Secretary of War; in Europe, during this period, he assisted in the evaluation of V. T. fuses and electronic aids to bombing. In 1946, returning to the Bureau, he served in a succession of increasingly responsible posts, becoming chief of the Atomic and Radiation

Physics Division; in 1951, he went to Corona, California, to serve for two years as director of the then newly established Corona Laboratories. Dr. Huntoon was appointed associate director for physics at the Bureau in 1953, and deputy director in 1958. He was born in Waterloo, Iowa, in 1909, studied at Iowa State Teachers College, and took his Ph.D. degree in experimental nuclear physics at the State University of Iowa in 1938.

Dr. J. C. Schoonover

Dr. Irl C. Schoonover has for the past five years been an associate director of the National Bureau of Standards, serving as principal staff adviser to the director on programme development, co-ordination and evaluation. Dr. Schoonover's thirty-year association with the Bureau has included the organization and direction of basic research programmes in the properties of materials, particularly at extremely high temperatures. He is well known for his direction of a research programme on dental materials, and was a pioneer in research on polymer structure at the Bureau. His work and leadership provided an integrated approach to studies of the chemical and physical properties of long-chain molecules in relation to structure. Dr. Schoonover received the Department of Commerce Superior Accomplishment Award in 1946 for his work on refractory materials, undertaken during his secondment to Los Alamos, and in 1961 he was awarded the Department of Commerce Gold Medal for Exceptional Service, being cited for "extraordinary versatility as a scientist-executive, and . . . exceptional leadership". Dr. Schoonover was born in Belington, West Virginia, and studied at Davis and Elkins College and George Washington University. He gained M.A. and Ph.D. degrees from Princeton University.

Dr. A. T. McPherson

Dr. A. T. McPherson has been associate director of the Office of Technical Services of the Department of Commerce for the past sixteen months. He worked there with Government agencies and national standards organizations in developing a new programme of inter-American co-operation on standards. Prior to this, Dr. McPherson had for ten years been an associate director of the National Bureau of Standards, co-ordinating committee activities on codes and specifications, and directing calibration and testing services throughout the Bureau. His investigations at the Bureau have included work in the fields of gas chemistry, electrical insulation, natural and synthetic rubber, and high polymers. From 1943 until 1951 he was chief of the Organic and Fibrous Materials Division, when the major part of his own scientific work was concentrated on rubber research. During the Second World War he served as a technical adviser on the Rubber Survey Committee, and was instrumental in the application of numerous new techniques in the making of both natural and synthetic rubbers. Dr. McPherson was born in Marceline, Missouri, and studied at Trinity University and the University of Texas. He was awarded a Ph.D. in chemistry by the University of Chicago in 1923.

R. B. Scott

Russell B. Scott has for the past ten months served as acting director of the Boulder Laboratories (Colorado) of the National Bureau of Standards. He was chief of the Cryogenic Engineering Laboratory at Boulder from its establishment in 1954 until his appointment as acting director. The Cryogenic Laboratory is one of three which comprise the National Bureau of Standards Laboratories at Boulder, the others being the Central Radio Propagation Laboratory and the Radio Standards Laboratory. Mr. Scott is a veteran of thirty-five years service in the cryogenic field with the Bureau, beginning with a post in the low-temperature section in Washington Laboratories in 1928. During the Second World War he was involved in the work of determining properties of uranium compounds, in support of the Manhattan Project. In 1948 he was appointed chief of the Cryogenic Physics Section in Washington. Mr. Scott was born in Ludlow, Kentucky, in 1902, and studied at the University of Cincinnati and the University of Kentucky. He was awarded an M.S. degree in physics by the University of Kentucky in 1928.

Research Contracts Awarded by the International Atomic Energy Agency

The two-hundredth research contract awarded by the International Atomic Energy Agency since this programme, intended to promote the peaceful uses of nuclear energy, began in 1958, was recently given to the Lovanium University at Leopoldville, Congo. In addition, 165 contracts were renewed during that period. The cost of the programme so far amounts to 2,923,035 dollars (1,770,469 dollars for the original 200 contracts and 1,152,566 dollars for 162 renewals). Out of this total 2,447,292 dollars were paid out of the Agency's own funds and 475,743 dollars were provided by the United States under an agreement concluded in 1960 between the Agency and the United States Atomic Energy Commission. The following is a breakdown of research contracts awarded by the Agency:

Subject category	Number of contracts placed or renewed	Amount allocated in U.S. dollars
Radioactive waste management and environmental research	56	508,158
Health physics and radiation protection	90	573,382
Radiobiology	81	697,697
Safeguards methods	14	235,520
Investigations involving the use of reactors	11	171,685
Radioisotope applications in agriculture	58	307,650
Radioisotope applications in hydrology	9	67,185
Radioisotope application in medicine	41	335,158
Miscellaneous	5	26,600
Total	365	2,923,035

The research to be carried out in Leopoldville at the *TRICO* reactor Centre should help to elucidate various affections of bone frequently found in inhabitants of that region, and caused by leprosy, smallpox and other diseases or by nutritional deficiencies. The Agency will provide radioisotopes as well as various other supplies and equipment worth 7,750 dollars.

Science in Sixth-form General Education

Part 2 of the Science and Education Report *Science in Sixth-Form General Education*, issued by the Association for Science Education, complements the Policy Statement previously issued by outlining the proposals of the Panel for courses which aim to give some understanding of the methods of science and appreciation of the effects of science on everyday life (Pp. 62. London: John Murray. Published for the Association for Science Education, 1963. 2*s*. net). Besides indicating the general principles of such courses, the Report presents detailed suggestions for courses on the nature of scientific thought; cosmology; energy; matter; life; behaviour; environment; and science and society. They are not intended to provide a syllabus to be studied in full, but rather to offer a broad field of suggestions which may assist teachers to devise their own courses. For the first course, for example, a historical and methodological approach and a logical and philosophical approach are outlined, with adequate bibliographies, and these bibliographies are frequently supplemented by lists of film-strips and films. The Report is intended to be read in conjunction with the Policy Statement and with the other three sections of Part 1, dealing with physics, biology and chemistry, respectively, for grammar schools. It is an admirable piece of work on

which the Association as well as the compilers are to be warmly congratulated. If it is widely and wisely read it could do a great deal to remove the weaknesses in education which have been the subject of present-day complaints, and it behoves the universities to make sure that no obsolete entrance requirements are allowed to frustrate the adoption in the schools of courses of the type herein proposed.

Measurements of Standard Frequency Transmissions

Measurements of the deviations of standard frequency transmissions have been made for a number of years by the Standards Division of the National Physical Laboratory, Teddington. Publication of these values, which related to Rugby transmitters, *MSF* 60 kc/s and *GBR* 16 kc/s, and the Droitwich 200-kc/s transmitter of the British Broadcasting Corporation, were discontinued in July 1962 when the journal in which they had appeared ceased to exist. Arrangements have now been made between the Director of the National Physical Laboratory and the Council of the British Institution of Radio Engineers for these standard frequencies to be published each month in the Institution's journal, *The Radio and Electronic Engineer*. The first set of values relating to the month of June 1963 were published in the July 1963 issue. A short communication from the National Physical Laboratory explaining the methods of measurements appears in *The Radio and Electronic Engineer* for July.

Studies in Density Difference Phenomena

The Department of Scientific and Industrial Research has granted £38,000 to Prof. W. Frazer and Dr. D. I. H. Barr, of the Civil Engineering Department of the Royal College of Science and Technology, Glasgow, in aid of integrated field and laboratory studies in density difference phenomena. The grant will allow for the extension of the present laboratory apparatus in which basic studies of the phenomena are carried out, and will enable the College to purchase and man a vessel with which intensive field studies can be initiated.

Density currents are set up in bodies of water when a flow differing in density from the receiving body is introduced. This can occur in many ways—by the fresh water from a river entering an estuary or the sea; by hot circulating water from the cooling system of a thermal power station being discharged into the sea or a river; and by the discharge of a sewage outfall. Mixing does not occur immediately and in many cases the introduced water can be traced for considerable distances. A striking example is the fact that the fresh-water flow from the River Amazon can be traced for hundreds of miles from the mouth of the river. The economic importance of the study of the phenomena is obvious; the currents set up in an estuary can play a very large part in the movement of sediment, and the Clyde Navigation Trust has made a grant of £8,000 to intensify work on this aspect of the subject in the River Clyde. In a thermal power station it is important that the hot circulating water issuing is not taken back into the system. This latter problem has been the subject of investigation at the College for six years, and studies have been carried out on two large hydraulic scale-models of the circulating water systems of Methil and Cockenzie Generating Stations by the Civil Engineering Department on behalf of the South of Scotland Electricity Board. At present, Prof. Frazer is advising on the similar problem which may arise in connexion with the proposed 2,400-MW station at Longannet in Fife. This will involve the construction by the South of Scotland Electricity Board of a very large hydraulic scale model of the Forth Estuary.

Television in the Medical School

An edited version of the verbatim transcript of the proceedings of the symposium *Television in the Medical School*, arranged by the Association for the Study of Medical Education and the Scientific Film Association at the London Hospital Medical College, May 10–11, 1961, has now been issued (Pp. v+73. Edited by Charles Engel and John Ellis. London: Association for the Study of Medical Education, 1963). It includes the papers presented at the session on television in research, dealing with basic theory, radiology, microscopy, endoscopy–ophthalmoscopy, and behaviour study, and the subsequent discussions; those presented at the sessions on television in teaching, dealing with present-day applications and investigations of television in American medical and dental schools; the application of television in preclinical teaching; in teaching histology; in teaching psychiatry; television endoscopy in clinical teaching; and clinical applications in German universities, as well as the ensuing discussions. Finally, it includes the papers presented on installations and on minimum basic equipment for television, and the replies from a panel answering questions on equipment and staff given at the session on practical requirements and cost of television in the medical school.

Soil Survey of Great Britain

Chief credit for the early steps in Britain on the examination of soils in the field, based on Russian, and later American, concepts of pedogenic processes and profile development, must be attributed to a small group of soil scientists including the late Prof. G. W. Robinson, Mr. Morley Davies, Sir William Ogg and Prof. T. Wallace. Meetings were held in various parts of the country to compare notes, discuss classification and initiate mapping. It was not until after the War, however, that the survey of soils was undertaken on a serious scale; it became one of the responsibilities of the Agricultural Research Council with the formation of the Soil Survey Research Board and an annual report of the work completed and in progress is issued; the present one provides the reader with an excellent account of the rapidly increased volume of information available on the soils of Great Britain (Report No. 15, 1962. Pp. vi+48. London: Agricultural Research Council. Obtainable from H.M.S.O., 1963. 5*s*. net). The scientific staff of the Soil Survey now numbers more than fifty; about two-thirds are employed in England and Wales with headquarters at Rothamsted, the remainder being in Scotland with headquarters at the Macaulay Institute. Frequent exchanges of views among surveyors are designed to maintain agreement in classification and nomenclature, and memoirs are published to explain and supplement the information on the maps. It will take many years to complete the soil map of the whole country; rapid reconnaissance is helpful, but detailed surveying is essential, and the effort spent has already been justified in the successful application of the results in agricultural and forestry problems. In addition to the regular mapping programme, assistance is frequently given in special surveys for such activities as Nature reserves, restoration of open-cast sites, archæological excavations, husbandry farms and field experimentation. An important contribution has been made in the production of a soil map of Europe, and officers are from time to time seconded to start or advance surveys of economic importance abroad.

Bibliography of Seismology

The Bibliography of Seismology continues its valuable work. It is compiled by J. H. Hodgson and F. E. Langill and published by the Dominion Observatory, Ottawa, for the Canadian Department of Mines and Technical Surveys. Nos. 5–10, Volume 22, which have been recently published, deal with work published during the years 1959, 1960 and 1961 and together contain 2,954 items. Seismic prospecting provides 533 items, studies of crustal structure 140 entries, and studies of surface waves 166 notes. The

origin of earthquakes, including fault plane mechanism, occupies 146 items, and there are 119 titles of publications on seismic instruments. An important group concerns 28 papers on Antarctic seismicity.

A Special Mechanism for some Antarctic Earthquakes

T. HATHERTON and F. F. Evison have written on this question in the *New Zealand Journal of Geology and Geophysics*, 5, No. 5, 864; December 5962. Frequent small earthquakes recorded at Scott Base constitute the main seismic activity so far discovered within Antarctica. Prominent in many Scott Base seismograms is a sinusoidal wave of period 1·5–2 sec, with an onset velocity of about 650 m/sec; this has been interpreted as an air-coupled wave associated with flexural waves in the Ross Ice Shelf. Other unusual features of the earthquakes also suggest that they are caused by fractures in the ice near the Shelf edge, leading to the calving of icebergs.

"Interchange Reactions of Disulphides"

THE following references were omitted from the communication under the above title, by Dr. E. R. Cole, which appeared on p. 1083 of the June 15 issue of *Nature*:

The Society for Applied Bacteriology

AT the annual meeting of the Society for Applied Bacteriology, held in Aberdeen on July 16, the following were elected officers of the Society: *Honorary President*, Dr. T. Gibson; *Honorary Secretary*, Dr. Ella M. Barnes; *Honorary Treasurer*, Mr. G. Elis Jones; *Honorary Editors*, Dr. D. J. Jayne-Williams and Mr. G. Sykes; *Honorary Publications Manager*, Mr. A. H. Walters; *Honorary Advertising Manager*, Mr. E. J. Mann; *Members of Committee*, Dr. Christina M. Cousins, Dr. Elizabeth M. Harper, Dr. A. Hurst, Dr. J. G. Murray, Dr. Agnes A. Nichols, Dr. Patricia M. Scholes, Dr. A. Seaman, Dr. F. A. Skinner, Dr. Joan Taylor. Dr. J. R. Norris, was co-opted as an *Honorary Assistant Secretary*.

Courses at Sir John Cass College, London

THE following courses will be held at Sir John Cass College, London, during the academic year 1963–64: statistical methods in scientific and industrial research (twenty lectures on Monday evenings, commencing September 23); medical laboratory techniques (commencing September 23); domestic and industrial fuel, part 1 (twelve lectures on Tuesday evenings, commencing September 24); spectrochemical analysis (twelve lectures on Wednesday evenings, commencing September 25); general technology of petroleum (twenty-two lectures on Thursday afternoons, commencing September 26); molecular spectroscopy (fifteen lectures on Friday evenings, commencing September 27); solid-state physics (commencing October 1); domestic and industrial fuel, part 2 (fifteen lectures on Wednesday evenings, commencing October 2); fundamentals of microbiology (thirty lectures on Wednesday evenings, commencing October 2); fuel plant technology (twenty-one lectures on Wednesday evenings, commencing October 2); applied microbiology (thirty lectures on Thursday evenings, commencing October 3); solid fuels (seven lectures on Thursday evenings, commencing October 3); electronic computing systems, part 1 (twelve lectures on Wednesday evenings, commencing October 23); liquid fuels (seven lectures on Monday evenings, commencing January 13); patents and industrial design protection (eight lectures on Thursday evenings, commencing January 16); distillation (eight lectures on Friday evenings, commencing January 17); electronic computing systems, part 2 (twelve lectures on Wednesday evenings, commencing January 15); vibrational spectroscopy (sixteen lectures on Wednesday evenings, commencing February 26); trade marks (four lectures on Thursday evenings, commencing April 30); advanced mathematics four-year course for full-time or part-time students); petroleum and petroleum products (two-year evening course); mathematics (two-year evening course to Advanced Level General Certificate of Education standard). Further information can be obtained from the Secretary, Sir John Cass College, Jewry Street, Aldgate, London, E.C.3.

Announcements

SIR HANS A. KREBS, Whitley professor of biochemistry in the University of Oxford and 1953 Nobel Prizewinner for Physiology and Medicine, has been appointed official visitor to the British Baking Industries Research Association for the next five years. Dr. T. F. Macrae, who has been an official visitor to the Research Association for the past five years, has accepted re-appointment for a further three years.

THE annual open day of the Water Research Association will be held at its new Research Station at Medmenham, Bucks (see *Nature*, 192, 803; 1961), on September 18. Further information can be obtained from the Water Research Association, Medmenham, Marlow, Bucks.

A CONFERENCE on "Diamond Abrasives and Tools", sponsored by De Beers Consolidated Mines, Ltd., will be held in Milan on October 7, during the eighth European Machine Tool Exhibition. Further information can be obtained from John Burls, Diamond Abrasive and Tool Conference, 40 Holborn Viaduct, London, E.C.1.

THE seventh international symposium of the Society of European Nematologists will be held at the West of Scotland Agricultural College, Auchincruive, Ayr, during September 9–13. The symposium will be concerned largely with the practical control of eelworm diseases of crop plants. Further information can be obtained from Dr. John Grainger, West of Scotland Agricultural College, Auchincruive, Ayr.

A CONFERENCE on "Management, Productivity and Industrial Relations", arranged by the Institute of Personnel Management, will be held at Harrogate during October 10–12. Four one-day courses are being arranged to precede the conference on October 10, dealing with the following subjects: the economics of personnel management; Trade Union membership and the non-manual worker; fringe benefits: philosophy, practice and dangers; recruitment, selection and training of selling staff. Further information can be obtained from the Institute of Personnel Management, Management House, 80 Fetter Lane, London, E.C.4.

AN ordinary meeting of the Midlands Section of the Society for Analytical Chemistry, on the subject of "Contributions to Analytical Chemistry by Younger Members of the Profession", will be held in the Chemistry Department of the University of Birmingham on September 18. Further information can be obtained from the Society for Analytical Chemistry, 14 Belgrave Square, London, S.W.1.

THE second Croxson Memorial Lecture of the Society of Non-Destructive Examination on "A Lifetime's Experience of Non-Destructive Testing in the Steel Industry" will be delivered by Mr. E. W. Colbeck, deputy chairman of Hadfields, Ltd., Sheffield, at the Conference Centre, Church House, London, on September 11. Further information and tickets can be obtained from the Conference Secretary, Fourth International Conference of Non-Destructive Testing, Institution of Mechanical Engineers, 1 Birdcage Walk, London, S.W.1.

THE ROYAL SOCIETY CLUB OF EDINBURGH

FROM the seventeenth and eighteenth centuries onwards, dining clubs have flourished in the United Kingdom. Shakespeare, Ben Jonson, Marlowe, Donne, Dekker, Dr. Johnson, Boswell and Sir Joshua Reynolds were all men who relished good food and conversation around a tavern table. This taste was shared by leaders of scientific progress; and out of the meetings of twelve or twenty enthusiasts, who met at the Bull-Head Tavern in Cheapside in 1650 to eat and drink, to experiment and to discuss science, was born the Royal Society of London. The Royal Society Club, unofficially known as the "Royal Philosophers", dates its minutes from 1743, but, probably, became a regular dining club about 1725.

Dr. Douglas Guthrie, in a recently published volume, ably records the leading features of an equally select club*. He begins with a brief account of the Royal Society of Edinburgh, which was founded in 1783. This arose from the amalgamation of a Society for the Improvement of Medical Knowledge, dating from 1731, and a Philosophical Society (for Science and Literature) which had existed from 1739.

The Royal Society Club was founded in 1820 "with the view of promoting the objects of the Royal Society". Membership was limited to forty-six Fellows of the Society elected by ballot. Since 1950 the number has been raised to sixty. The Club met at various Edinburgh hotels up to 1909, but now normally meets in the rooms of the Royal Society in George Street. Dinners have also been held in or near Edinburgh.

* *A Short History of the Royal Society Club of Edinburgh* 1820 *to* 1962. By Douglas Guthrie, with a foreword by Prof. E. L. Hirst, president of the Royal Society of Edinburgh. Pp. 40, illustrated. Published privately by the Royal Society Club, Edinburgh, 1962.

Interesting sketches are given of distinguished members of the Club. Sir Walter Scott was the third president of the Royal Society of Edinburgh (1820–32) and the only 'literary' president. He was an original member of the Club, and was præses (chairman) at the dinners of March 6, 1820, February 5, 1827, December 3, 1827, and January 18, 1830. He attended on other dates and was elected an honorary member in 1831. Other eminent members are mentioned, for example, James Skene, the first secretary, antiquary and close friend of Sir Walter; Lord Meadowbank, the judge; Sir Archibald Geikie, geologist; the versatile Prof. John Stuart Blackie; Sir Robert Christison; Lord Playfair; Lord Kelvin; and coming to later times, Dr. G. A. Gibson, Sir D'Arcy Thompson and the great bacteriologist, Sir Robert Muir. In the nineteenth century music and song added to the conviviality of the dinners, and some of the witty songs sung were composed by the members. The Club has entertained many distinguished guests, including the Crown Prince of Sweden, the Prince of Monaco, Captain Peary, Fridtjof Nansen, Dr. Sven Hedin, Sir J. J. Thomson, the physicist, Lord Balfour, statesman and philosopher, and Sir Arthur Keith. An account is given of two other clubs (now extinct) for more junior Fellows, namely, the Royal Society New Club and the Royal Society Supper Club. The book is illustrated by portraits of certain members.

The Club has been fortunate in persuading Dr. Guthrie, who has been for many years a devoted member both of the Royal Society of Edinburgh and of the Royal Society Club, to write its interesting history.

ARTHUR MACNALTY

RESEARCH INTO EDUCATION IN BRITAIN

IN a debate in the House of Commons on July 24 on the Schools Council for Curriculum and Examinations which was opened by Mr. J. Boyden, who expressed some concern about the establishment of such a council, Mr. F. Wiley referred to proposals made by the universities to the Minister for Science for the establishment of an educational research council. Mr. Wiley stressed the need for conditions of support which preserved for the individual worker the intellectual initiative essential for creative work. The universities, he said, pointed out that an educational research council should be independent of the executive departments of the Government, and directly responsible, not advisory, for the expansion of research, including research into problems of primary, secondary and tertiary education in Britain as a whole. They suggested a council of about 12 members, chosen for their distinction and bringing together wide experience in research. They would not be representative, and this body was the antithesis in character of the council of 58 or 59 which the Minister of Education was proposing to establish.

In reply, the Minister of Education, Sir Edward Boyle, said that he had convened a meeting on July 19 to discuss a memorandum which he had circulated widely, and which was inspired by the central thought that curriculum development on the scale now required demanded the willing and enthusiastic co-operation of all partners in Britain's educational service. The discussion was of extremely high quality, and at the end of the meeting a resolution was passed which (*a*) noted that there was wide support for the proposal to establish co-operative machinery in the fields of school curriculum and examination; (*b*) appointed a working party, with Sir John Lockwood as chairman, comprising one representative of each of the bodies present at the meeting, together with assessors and a secretariat appointed by the Minister for Education, to consider how effect could best be given to the matters discussed and to make recommendations; (*c*) agreed to reconvene to consider and reach conclusions on the working party's recommendations.

On the general issue of research, Sir Edward Boyle said that while the sum allotted in this year's Estimate was only about £70,000, the total cost of all the projects being undertaken would, when completed, be between £200,000 and £250,000. One of the difficulties in this field, besides isolating the specific fields, was to find teams capable of doing full justice to them. Sir Edward assured the House that he was fully aware of the great importance of the research work in progress and for the future he thought that team work on curriculum and methods should proceed in a context which ensured the exchange of ideas between different teams. He pointed out that the curriculum study groups and the inspectorate were not entirely separate, the former including many of the ablest inspectors. He had discussed these ideas with a representative meeting of inspectors and there was no intention to diminish the role of the inspectorate, which was even more important in the educational system than many people realized. There was, however, a danger that some central bodies could be pushed into

oxtending their proper terms of reference, and he did not wish the establishment of the curriculum study groups to lead towards centralized control of the curriculum or towards misdirected central influence on it. If a schools council were set up, however, he would wish it to be more than a purely advisory body and that it should possess complete autonomy in all matters which did not fall within the Minister's statutory powers and responsibilities. With regard to the size of any such council, Sir Edward insisted that education in Britain was a shared service, and accordingly such a council must bring together the Ministry and local authorities and the teachers. He hoped that the council would also include not only representatives of those concerned with the day-to-day work of education in the schools, but also some who could point out lines of research on issues which might be overlooked by others, members who were competent to challenge the Ministry and Britain's traditional day-to-day approaches to the kind of research which was most needed.

The proposals mentioned by Mr. Wiley were sent to the Minister for Science by the heads of departments and institutes of education of universities in England and Wales. They refer to the danger of a patchwork of short-term projects and base their proposals on the organization of the existing Research Councils responsible to Lord Hailsham.

TRANSLATIONS OF LITERATURE ON NUCLEAR ENERGY

THE European Atomic Energy Community (Euratom), the United States Atomic Energy Commission, and the United Kingdom Atomic Energy Authority have agreed to pool their efforts in order to collect and disseminate information on translations of nuclear literature, in particular of documents originally written in languages unfamiliar to the Western reader. An information office 'Transatom' has been set up at the headquarters of Euratom in Brussels for the collection of data concerning translations of interest, and a monthly guide to nuclear literature in translation, *Transatom Bulletin*, compiled by Euratom is published by the Elsevier Publishing Company, Amsterdam. The *Bulletin* is in English and provides a unique survey of translations into English, French, German and Italian, of articles, monographs, books, reports, etc., in the field of nuclear science and technology originally published in the non-Western world. Precise bibliographical data of the original Russian, East European, Japanese and Chinese documents are included in the *Bulletin*, together with the addresses of the translation agencies which can supply copies of the translations listed and the conditions of availability of the translations. Certain journals receive cover-to-cover translation and a separate list of these is printed in every issue of the *Bulletin*. The various entries in the *Bulletin* are classified under fourteen headings, covering general and specialized areas of science and technology in which nuclear energy is either fundamental or has found some application.

A list of translations in preparation, but yet not completed, which may be of special value to many organizations so as to avoid duplication of effort and unnecessary expense, is an added feature of the *Bulletin*. Both author and source indexes are given in every issue of the *Bulletin*, and cumulative quarterly indexes are included in the Nos. 3, 6 and 9 issues, with an annual cumulative author and source index in the final (No. 12) issue of the year and volume. The *Bulletin* is now in its third year of publication.

A new publication of Euratom, *Euratom-Information* *, is to be published bi-monthly. The research undertaken by Euratom which is now five years old is beginning to give rise to a rapidly increasing number of reports, at present at about one a day, and the new publication will act primarily as a periodical catalogue of the reports. The contents of the first issue of *Euratom-Information* is divided into five sections. The first contains a list of 104 scientific and technical publications; the second 33 patents; the third the research contracts signed by the Euratom Commission up to December 31, 1962; the fourth details of the research activities which the Commission plans to carry out as from January 1, 1963, and in which individuals and organizations within Euratom can collaborate; and finally, a statement of the Euratom–United States of America joint research and development programme. In the first section, where the publication referred to is not in English, the foreign language summary together with the translation of both the title and summary are given. Details of how to obtain copies of the reports and publications listed are included.

S. WEINTROUB

* *Euratom-Information*, Vol. 1, No. 1 (May 1963). (A publication of the European Atomic Energy Community.) Pp. 1–81. Published at two-monthly intervals. (Düsseldorf: Handelsblatt, G.m.b.H., Kreuze-Strasse 21, 1963.) Annual subscription 15 dollars.

REFLECTED LIGHT MICROSCOPY

THE quantitative methods which can be applied to the study of opaque minerals (natural and synthetic) under the polarizing microscope are the measurement of reflectivity, of rotation properties, and of micro-indentation hardness. Recent advances in these methods have brought them to the point where it is believed that they can be generally applied in a way similar to the use of optical methods in the identification of transparent minerals.

With the view of disseminating knowledge of these methods as widely as possible, a small committee of British mineralogists was set up to organize an international Summer School. With the aid of a generous grant from the Scientific Affairs Division of the North Atlantic Treaty Organization, an advanced study course was held during June 23–July 2 in the Department of Mineralogy and Petrology, Cambridge. There were thirty-one members, including eight observers, drawn from twenty-three different countries; all except two of those in the observer category were mineralogists engaged in academic work.

The basic techniques and theory were covered in seven lectures and practical demonstrations, after which the members divided into two sections (ore minerals and coal petrology) for a further six lectures followed by practical work in either section. Each member had a total of thirty hours of practical work, and in addition there were three colloquia. Throughout the course emphasis was placed on the practical aspects of quantitative measurements, and this was made possible by the generous loan of equipment by several firms. Much of the apparatus, which included reflecting-polarizing microscopes, monochromators, photometers and micro-indentation hardness testers, was of recent design, and the opportunity was taken of obtaining comments from the members on the equipment.

Further information about this Summer School can be obtained from the secretary, Dr. N. F. M. Henry, Department of Mineralogy and Petrology, Cambridge.

ASIA AND OCEANIA CONGRESS OF ENDOCRINOLOGY

THE second Asia and Oceania Congress of Endocrinology was held in Sydney during May 28–June 3 under the auspices of the Endocrine Society of Australia. The president of the Congress was Prof. C. W. Emmens, and Prof. T. Miyake (Japan), Dr. H. D. Purves (New Zealand) and Prof. V. M. Trikojus (Australia) as vice-presidents.

One hundred and eighty delegates participated in the Congress, including fifteen from Japan, six from New Zealand, five from the Philippines, four from both Great Britain and the United States, two from India, one from Hong Kong and one from Italy. Eighty papers were read from 120 offered.

Prof. A. S. Parkes (Physiological Laboratory, Cambridge) opened a symposium on "Regulation of Fertility", and discussed climatic, social and nutritional factors. Rapid-acting and neural effects were differentiated from the slower-acting responses mediated via the anterior pituitary. The importance of smell as an exteroceptive factor working through slowly acting neurohumoral mechanisms was discussed. Related papers, including a number from workers in Japan and from a group in Sydney on various aspects of œstrogenic and anti-œstrogenic effects, followed the opening paper.

Dr. H. D. Purves (Endocrinology Research Department, Medical Research Council of New Zealand) opened a symposium on "Control of Thyroid Secretion" and discussed aspects of the feed-back mechanism in relation to control of thyroid function. He was followed by Prof. T. Miyake (Kyoto, Japan), who reported on clinical studies of thyroid hormone metabolism, and a series of papers from groups working in New Zealand, in Melbourne and in Adelaide were presented.

A symposium on "Hormonal Response to Environment" was led by Prof. E. C. Amoroso (Royal Veterinary College, London), who spoke on "The Endocrine Environment of the Fœtus" and discussed aspects of the complicated hormonal environment in which the developing mammalian organism grows pre-natally. This was followed by papers from a group in Melbourne on electrolyte balance in ruminants, and by a paper on the suckling stimulus in marsupials from workers in Canberra, and by two papers from Indian workers.

Dr. M. S. Raben (Boston, United States) opened a symposium on "Protein Hormones in Growth", and reported investigations of metabolic and clinical effects of human growth hormone. Problems concerned with the production of a satisfactory preparation were summarized and details given of metabolic work on selected patientf receiving these preparations. The characterization os pituitary growth hormones from various species was described by a group working in Sydney.

In addition to these symposia a number of papers on adrenal physiology, comparative endocrinology, steroid hormones and hormone assay were presented in concurrent sessions.

The interest and prominence of a session on hormone assay, particularly of steroid hormones, indicated the concern of many endocrinologists with details of basic methods which will enable reliable results to be obtained by workers in different laboratories and thus lead to comparisons which have some significance.

On the final day a group of papers on clinical endocrinology was presented, and during the afternoon a plenary session was held with The Royal Australasian College of Physicians, which was celebrating its Jubilee in the week following the Congress. The session was opened by Dr. R. F. Escamilla (San Fransisco), who spoke on "Stimulation of Growth in Short Children: Experiments with Human Growth Hormone", and papers were presented from the United States, Japan, India and Australia on various clinical aspects of human growth hormone, anabolic steroids, idiopathic hirsutism, corticosteroid treatment and diabetes in pregnancy.

It is apparent from the general interest of the participants and the quality of the papers presented that the study of endocrinology is being actively pursued in a number of centres in the Asia and Oceania region, and that a high standard is being maintained.

A factor in the success of the Congress was associated with the opportunities afforded delegates to make new, and renew old, acquaintances. The site of the Congress, a section of the Chemistry School, University of Sydney, and the limited number attending were both conducive to a free circulation of members during lunch and tea periods. The spirit of informality pervaded the lecture rooms and led to that most important aspect in the success of a Congress, lively and friendly discussion.

Acknowledgement should be made to the Executive Committee for their organization and to Dr. P. J. Claringbold (C.S.I.R.O. Division of Animal Genetics), the secretary to the Congress, for his excellent administration, which contributed largely to its success.

The third congress will be held in Manila in January 1967.

I. G. Jarrett

VOLTA BASIN RESEARCH PROJECT

By Prof. G. W. LAWSON
Department of Botany, University of Ghana, Legon

WHEN the Volta Dam in Ghana is completed next year a lake will begin to form which will eventually cover an area of 3,275 square miles. This will be the largest man-made stretch of water in the world. The water-level will begin to rise in about September after the rainy season of 1964 and will reach the 200-ft. contour in the first year, but the final level will not be reached until some years later. The Volta Scheme will primarily provide hydro-electric power for an aluminium smelter at the new port of Tema which will ultimately produce 120,000 long tons of aluminium per annum, mostly for export. Ghana is and has always been an agricultural country relying mainly on the export of cocoa for the foreign exchange needed to buy manufactured goods. The availability for the first time of cheap electricity means that conditions will be created for a rapid industrial revolution with an inevitable rise in standards of living throughout the country.

Additional benefits from the scheme will include a large freshwater fishery and a cheap inland water transport system. It is also planned to grow crops, especially rice and sugar cane under irrigation. Undoubtedly the impact on Ghana's economic life will be tremendous.

The creation of the lake will also, however, have many important biological implications, the most important and immediate of these being the removal and rehabilitation of more than 70,000 people from the area to be flooded. This work is being undertaken by the Volta

River Authority, a Government body set up to control all aspects of this far-reaching scheme. The transplantation of these people, consisting of many different tribal, language and religious groups, and about who there exists little written information, creates far-reaching sociological problems.

As with every major development project, it is necessary, by careful advance study and planning, to safeguard against certain dangers which so large a change in the environment is capable of provoking. One such danger, in this case, is that certain water-borne diseases such as bilharzia and onchocerciasis (river blindness), already serious in Ghana, will become accentuated. There is also the undoubted possibility that aquatic weeds may become a serious problem as they did at Kariba Lake in Central Africa, where more than 200 square miles of water is covered by a dense mat of *Salvinia auriculata* adversely affecting fisheries and making lake transport difficult or impossible.

Apart from these intensely practical problems many more academic but highly interesting phenomena require investigation. A biological and physical survey needs to be undertaken now to ascertain the populations of fish and other animals that at present inhabit the Volta River and its tributaries and the conditions under which they exist. Likewise the phytoplankton will undergo a unique series of changes as the lake forms. On the human side there is much information to be gained about such subjects as the distribution of language groups and the social organization of the inhabitants of the Volta Basin area before they are moved. Several archæological sites need to be investigated. They do not compare in importance, of course, with the monuments in the Sudan which may be lost by the building of the high Aswan Dam, but in view of the relatively little that is known of the pre-history of West Africa they are of distinct academic interest.

Not only the Basin area but the area below the Dam will be affected both biologically and economically. The present seasonal flooding enriches both the land used for agriculture and the numerous creeks used for fishing by the riverine population. During the dry season, when the river is low, collection of river clams (*Egeria radiata*) is carried out. This flourishing industry, which employs several thousand women and is worth about £100,000 a year, will be threatened by the eventual steady flow which will be too fast throughout the year for collection to take place and which may also affect the delicate balance of saline and fresh water in which the clams thrive. Transplanting of the clams to more favourable areas may be possible. Such problems must be investigated and possible solutions to them need to be attempted before it is too late.

These are just some of the things that cry out to be done in the little more than a year that remains before flooding, and in view of the urgency that exists the University of Ghana has decided to launch a Volta Basin Research Project. Work by existing staff has already commenced on several aspects of research connected with the project and it is intended to recruit Research Fellows to undertake specific problems. The Project Committee will welcome any outside assistance and will endeavour to give every possible help to individuals or groups who wish to be associated with it.

The initial financing of the project is being provided by the University, and the project has the support and approval of the Volta River Authority and the United States A.I.D., who, it is hoped, will be able to contribute to its development both as regards equipment and personnel.

ANALYSIS OF THE LIFE-CYCLE IN MAMMALIAN CELLS

UNDER this title Defendi and Manson[1] have recently published results obtained with a few normal and aberrant types of mammalian cells, and from these results, and from a selection of information taken from the literature, they have generalized "that most mammalian cells of normal and tumour origin, *in vivo* or *in vitro*, pass a similar period of time in DNA synthesis and in preparing for mitosis irrespective of the generation time". It is possible that this conclusion may ultimately prove to be justified, but at the moment the available evidence scarcely appears to be adequate, and a more appropriate conclusion might be that for most mammalian cells of normal and tumour origin no information exists at all.

They further conclude that "the *primum movens* of cell division has to be searched for not at the initiation of mitosis but farther back in the cycle at the time of initiation of DNA synthesis". This has, of course, been obvious for a long time, although the important proviso must be added that the actual point at which the cell commits itself to prepare for division may well be earlier than the point of initiation of DNA synthesis. The beginning of DNA synthesis is merely the earliest point that can be observed with present-day techniques.

Finally, they quote the conclusion of Gelfant[2] that adult mammalian epidermis is an exceptional tissue in that it contains a unique population of cells which have completed DNA synthesis but which remain quiescent for "an indefinite period of time, acting as a reservoir of cells immediately ready to undergo mitosis". Unfortunately, for a variety of reasons Gelfant's conclusions cannot be accepted; it is sufficient to note that his published results are statistically inadequate. However, as is shown here, there may well be a half-truth in this particular conclusion.

In view of the confusion which may be created it seems necessary to set out the most significant of the evidence now available regarding the mitotic cycle in adult mammalian cells. However, before doing this it is necessary to analyse, name and define the phases through which a regularly dividing cell passes (Fig. 1). The literature contains a varied and sometimes contradictory terminology.

Cycle of cell growth and mitosis. The generation time is the time taken by a cell to pass through the whole cycle, for example, from prophase to succeeding prophase. There is a large literature on the generation times of various tissues and cell types, and this has been well reviewed[3,4].

On present knowledge the whole cycle of cell growth and mitosis can be subdivided as follows:

(1) *Early interphase:* the period between the end of telophase and the time when the cell 'decides' whether to differentiate or to prepare for yet another mitosis (in the literature this phase is variously called "G 1", the "first growth phase", the "first gap", or the "presynthetic resting phase").

(2) *Dichophase:* a new name derived from διχο (expressing doubt between two ways ahead) and here used to define what may be the most interesting and important phase in the whole cell cycle, the "phase of decision" when within the cell a 'choice' is made between synthesis leading to differentiation and synthesis leading to division. The duration of this phase is unknown.

(3) *Prosphase:* a new name derived from προσ (expresing movement towards) and here used to define the whole

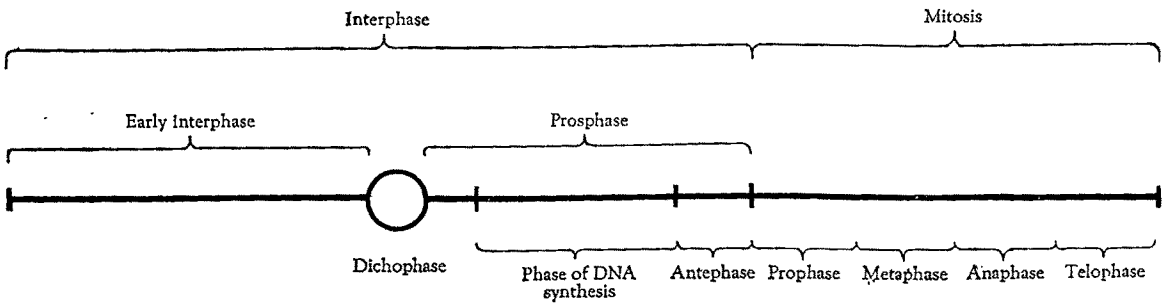

Fig. 1. The sequence of phases in the cycle of cell growth and mitosis. In dichophase a cell may be diverted to differentiate

period of preparation for mitosis. It extends from the end of the dichophase to the beginning of mitosis. All that is at present known is that during the prosphase the DNA content of the chromosomes is doubled, the spindle protein is at least partially synthesized, and an energy store is established for the use of the cell during mitosis[5]. The prosphase can be subdivided, but so far only two subdivisions have been clearly defined:

(*a*) *Phase of DNA synthesis:* this may begin at the same time as, or later than, the beginning of the prosphase, but no information is available on the point (in the literature it is called either "S" or the "synthesis stage", which are, in fact, general terms which should strictly be related to the whole of the prosphase). The duration of this phase has been accurately determined in several tissues by the use of tritiated thymidine.

(*b*) *Antephase:* this extends from the end of the phase of DNA synthesis to the onset of mitosis[5] (it is also called "G 2", the "second gap", or the "second growth phase", though no growth is evident, or alternatively the "predivision resting phase", though the cell is probably not resting). The antephase was originally defined as that stage which immediately precedes the visible prophase and in which an energy store is established[6]. There has since been some argument as to the time of establishment of this energy store, but in the case of mouse epidermis the evidence still favours the antephase as being most important in this connexion[7].

(4) *Mitosis*: the visible stages of cell division from prophase to telophase (in the literature it is often simply called "M"). The subdivisions of mitosis are too well known to need repetition.

In considering the time relations of these various phases within the whole cycle of cell growth and mitosis, it is immediately obvious that they must vary widely between the various cell types found in an adult mammal. Broadly and artificially speaking, three categories can be recognized: those with a short generation time of hours, those with a moderate generation time of days, and those with a long generation time of weeks, months or even years. A fourth category can also be defined to include cells that have suffered some pathological change.

Cells with a short generation time. Most of the attempts which have been made to time the durations of the various phases of cell growth and mitosis in the adult mammal have concerned tissues with a high mitotic rate, and this is understandable since with such tissues answers are more easily and rapidly obtained. However, it must be remembered that, in the adult mammal, tissues with a naturally high mitotic rate are the exception rather than the rule.

Examples of the results obtained with such tissues (Table 1) are taken from the precise analyses of the mitotic cycle in the duodenal crypts of Lieberkühn by Lesher *et al.*[8], and from the study of hair roots by Cattaneo *et al.*[9]. Descriptions of the techniques used have been given, for example, by Fry, Lesher and Kohn[10,11].

Table 1. Approximate Durations of the Phases of Cell Growth and Mitosis in Two Tissues with a High Mitotic Rate

Type of tissue	Early interphase	DNA synthesis	Antephase	Mitosis	Authors
Crypt of Lieberkühn	5 h	5 h	less than 2 h		8
Active hair bulb	3 h	7 h	1 h	1 h	9

It will be noted that the cells of both these tissues have a generation time of roughly 11–12 h. Since no shorter generation times are known, the cells of these tissues may be multiplying at the maximum speed that is possible in a normal adult mammal. If this were so, then it should follow that each of the separate phases of cell growth and mitosis is also being completed at the maximum possible speed.

Cells with a moderate generation time. Only one complete analysis of the phase times of normal cells with a generation time of days rather than hours appears to have been published to date, and this relates to mouse ear epidermis[12] (Table 2). However, since this was published, new information has been obtained which indicates that a full analysis of the behaviour of epidermal cells is likely to reveal a complex situation[7]. Setting aside the fact that the generation time of the basal epidermal cells may vary in different body regions, and even between different strains of mice[7], it is important to note that epidermis shows at least two remarkable differences from the pattern seen in Table 1. In the first place, it has been found that the duration of epidermal mitosis is very variable[7]. This has been determined using mouse ear epidermis *in vivo* and *in vitro*, and a brief selection of the kind of results obtained are shown in Table 3. Full accounts of this work will be published elsewhere, but the following points may be briefly noted: that the range of variation in the duration of mitosis in mouse ear epidermis *in vivo* and *in vitro* so far discovered is 1·5–5·3 h; and that in normal epidermis the duration of mitosis is proportional to the adrenaline concentration. In Table 3 the mice which were asleep or adrenalectomized had epidermis with a low adrenaline content, and so, too, did the control epidermis *in vitro*; the epidermis of the mice which were awake, like the epidermis *in vitro* with added adrenaline, had a higher content of this hormone.

Table 2. Examples of the Varying Duration of Mitosis in the Ear Epidermis of Adult Male Mice (ref. 7)

In vivo condition of mice			*In vitro* with 0·02 M glucose and oxygen	
Awake	Asleep	Adrenal-ectomized	Control	With 0·025 μg adrenaline/ml.
3·8 h	2·6 h	2·7 h	2·8 h	4·6 h

Table 3. Approximate Durations of the Phases of Cell Growth and Mitosis in the Ear Epidermis of Adult Male Mice

Early interphase	DNA synthesis	Antephase	Mitosis	Authors
483 h	30 h	4·6 h	3·8 h	12
—	—	as long as mouse remains awake or stressed	2·6–3·8 h	7, 13

The other important difference shown by epidermal cells is their behaviour in antephase[13]. While adrenaline can only slow down the process of mitosis, it can completely block the passage of a cell in antephase. It is the imposi-

tion of this blockage in a mouse when awake and its release in a mouse when asleep that gives rise to the well-known diurnal mitotic rhythm. The mitoses that develop during sleep are partly those of cells which at that time complete their preparations and partly those of cells which had completed their preparations previously while the animal was awake. It has been shown that the longer a mouse is forced to remain awake the higher is the number of mitoses developing during subsequent sleep[13]. It can now also be added that the higher the number of mitoses obtained in this way the faster each one passes to completion[7], but this is a phenomenon that will be analysed elsewhere.

It is important to notice that although a higher adrenaline concentration, found in animals when awake, causes an antephase inhibition and slows the passage of mitosis in the epidermal cells, these effects are not seen in the cells of active hair roots, which are epidermal derivatives[14]. Indeed, it appears probable that whereas tissues with a moderate mitotic rate may all be adrenaline sensitive, since so many of them are known to show a diurnal mitotic rhythm, tissues with a high mitotic rate may all be insensitive to adrenaline, since they evidently show no diurnal rhythm. It is significant that, after wounding, those epidermal cells that develop a high mitotic rate also lose their sensitivity to adrenaline[13].

In generalizing in this way it may, of course, be necessary to make an exception of such tissues as the vaginal and uterine lining epithelia, in which mitotic activity is hormone dependent.

In mouse epidermis the situation has been further complicated by the discovery that inhibition in antephase and during mitosis is due not to adrenaline itself but to an unstable complex formed between the adrenaline and some substance secreted within the epidermal cells. This substance is probably epidermis-specific, and it may be a protein. It has been proposed that tissue-specific substances of this kind, which may be common in the body, should be called chalones[15]. The existence of at least three separate chalones in the skin has so far been inferred[16].

This new information provides some explanation for what evidently happens when the epidermal mitotic rate rises: in sleep, as the rate of adrenaline secretion falls, the chalone–adrenaline complex breaks down and the mitotic inhibition is therefore removed; *in vitro*, as the adrenaline washes out from the epidermis (which it may do in a matter of minutes[17]) the same situation arises (this, incidentally, may explain the curious results reported to be obtained after cutting the skin and culturing *in vitro*[18]); while after wounding, it appears that it is the chalone itself that is lost from the adjacent cells so that adrenaline can no longer act as a co-factor to interfere with mitosis, and there is therefore no diurnal rhythm[19]. This last observation could lead to a suggestion that in tissues with a naturally high mitotic rate there may either be a lack of chalone with which adrenaline could combine to form a mitotic inhibitor, or alternatively that there may be a lack of the enzyme necessary to catalyse their combination.

To return to the main argument, it is now evident that in epidermis the higher the concentration of the unstable chalone–adrenaline complex the longer the antephase will last and the slower each mitosis will proceed. From results with mice stressed continuously it seems that the antephase may be prolonged for days[13], but in a normal mouse in a well-kept animal house it may not usually exceed the few hours of the normal waking period.

It is evidently only in this limited sense that in the words of Defendi and Manson[1] there exists "a special class of cells of the mouse epidermis . . . acting as a reservoir of cells immediately ready to undergo mitosis". However, it is possible that in a poorly organized animal house, where the mice are unusually stressed, there might sometimes be an unusually large number of cells arrested in antephase.

The release of cells from antephase blockage, whether *in vivo* or *in vitro*, must not be confused with the normal wounding reaction of damaged epidermis. This is a reaction which begins not in antephase but usually in already differentiated cells. The mitotic activity of wounded ear epidermis *in vivo* does not begin to rise until after some 36–48 h (ref. 19), which might be regarded as the time taken by the adjacent cells to revert to the undifferentiated condition and to pass through the prosphase to mitosis.

It is also possible that this reversion may itself be the result of the loss of chalone, although at the moment the evidence for this is only indirect.

Cells with a long generation time. In an adult mammal the various cell types can be arranged in a graded series from those with a short generation time to those with a generation time so long that most cells may never be replaced during the whole of life. Most connective tissues and most well-protected internal organs such as liver and kidney belong to this last group, and indeed, they give the impression that being fully differentiated they are all mitotically inert.

However, it is interesting to note that most of these tissues resemble epidermis in their ability to develop high mitotic activity after wounding, and in such a situation the cells dedifferentiate. There seem to be good grounds for suggesting that these tissues do not differ fundamentally from epidermis[15]; they may merely be under some tighter control mechanism which, if it is like that of the epidermis, may be based on a stable rather than an unstable chalone–adrenaline complex. However, at the moment this is mere hypothesis.

Abnormal cells. It is only in the light of the normal cycle of cell growth and mitosis, and of the mechanisms by which it is controlled, that any real understanding can be obtained of conditions in pathological growth. From time to time, and for one reason or another, normal tissues may produce within themselves abnormal cells which develop such an unusually high mitotic rate that the usual precise balance between cell wastage and cell gain is disturbed. However, such abnormal cells evidently show wide variations in their degree of independence from the normal tissue control mechanisms, and also possibly in the actual manner in which this independence has been achieved.

They are also evidently very varied in their generation times, and Bertalanffy[20] gives figures ranging from about 12 h to several days. It is tempting to speculate whether the generation time may be a function of the degree of independence achieved.

From an inadequate literature it would also seem that tumour cells may vary in their reactions to adrenaline since some have been reported to show a diurnal mitotic rhythm[21] while others have not[20]. Again, it seems possible that the presence or absence of the rhythm may depend on the degree of independence achieved by the cells. Thus the existence of a diurnal rhythm in a tumour could be taken to suggest that the cells may still retain some significant part of their normal chalone–adrenaline control mechanism, and such cells, like normal epidermis, might show an antephase and a mitotic phase of variable length.

Conversely, the absence of a diurnal rhythm in a tumour might mean that the cells no longer retain any significant part of their normal control mechanism. Such cells, like normal hair roots, might show phases of cell growth and mitosis which are both short and of relatively constant duration.

Conclusions. Perhaps the only conclusion to which no exception can be taken is that it is still too early to discern more than a vague outline of the type of mitotic control mechanism which must exist in the tissues of an adult mammal and which must determine both the onset and the duration of the various phases within the cycle of cell growth and mitosis. However, although what little is known relates to only one or two tissues, it would cer-

tainly be surprising if it were discovered that there is no common basis to the various control mechanisms of the various tissues. Mitosis itself is such a uniform process wherever it is found that the pattern of its control may be equally uniform, although, of course, it may be expected that each tissue will show its own specific variation within that pattern.

In the cycle of cell-growth and mitosis there is one period of outstanding interest and importance, and it is unfortunately the one about which least is known. This is the period here defined as the dichophase, the phase of unknown duration within which the decision is reached whether the cell's synthetic machinery shall be directed towards differentiation or towards preparations for yet another division.

The only slight information that can be deduced about the dichophase and about differentiation itself comes from the results of experiments on wounding and on 'compensatory hypertrophy'. In such experiments cells which have previously committed themselves to differentiate are seen to reverse this decision and to prepare once more for mitosis. The impression is gained that most cells that are not so highly differentiated that they can never again divide are in fact normally held in the differentiated state by some factor which, when it is withdrawn, releases the cells to revert back through the dichophase to their basic activities of growth and mitosis. After wounding and in 'compensatory hypertrophy' such a withdrawal is only temporary, and there is some evidence to support a hypothesis that the factor withdrawn may in fact be the chalone which is specific to the tissue in question[5,15,19]. On this argument the chalone may prove to be a basic part of the mechanisms both of differentiation and of mitosis inhibition, if indeed these mechanisms can be separated. Also on this argument differentiation may be regarded as an unstable state.

It may be noted incidentally that some indication of the speed with which a differentiated cell can return to the dichophase has been recorded for rabbit lens epithelium by Harding and Srinivasan[22], who have found that thymidine-incorporating cells first appear in the vicinity of a wound about 14 h after injury. This period may be roughly similar to that in epidermis, but other tissues, such as mouse hypodermis and mouse ear cartilage[7], probably take much longer. Whether such information gives any indication of the time normally taken to pass in the reverse direction from dichophase to the fully differentiated condition is, of course, debatable.

In a tumour, the undifferentiated condition shown by the cells is permanent. Theoretically this sort of change might occur in several ways: on the chalone hypothesis it could be due either to a failure to produce sufficient chalone or to a failure to react to what chalone is present. In either case, the failure might be one of degree only: the more complete it is, the more cells might be expected to dedifferentiate, the higher might be the mitotic rate, and the shorter might be the various phases of the cycle of cell growth and mitosis.

However, until a much clearer understanding has been obtained in normal mammalian tissues of the manner of control of the various cycle phases, of the factors that determine the choice made in the dichophase, and of the manner in which a differentiated cell is maintained in that condition, it is of little value to speculate on the conditions that may exist within cells that have suffered a pathological change.

Note added in proof. Since this article was written an important discovery has been reported by Pilgrim, Erb and Maurer (following article, p. 863). They have provided the first indication that in certain tissues not only may there be a diurnal rhythm in the number of cells in mitosis but also a similar rhythm in the number of cells in the phase of DNA synthesis. However, the available evidence is against their conclusion that the diurnal mitotic rhythm may be the delayed consequence of the diurnal rhythm in DNA synthesis. It appears more probable that there may exist two highly sensitive points in the mitotic cycle, the first during the transition from dichophase to prosphase (or to DNA synthesis) and the second during the transition from antephase to mitosis. It is now extremely important to discover whether both these points are sensitive to the inhibitory action of the same mitotic control mechanism.

Without making detailed comments on Prof. Bullough's communication, or on the very general scheme he proposes, we would like to rectify some of his statements presented in reference to our own communications.

(1) Prof. Bullough's statement in the initial paragraph is incorrect in minimizing the basis of our conclusions since, in addition to four tumour cell lines, we have tested three strains of human diploid cells which, by any criteria we can consider, are neither "aberrant" nor "pathological".

(2) While, of course, little is known about all the various factors involved in the preparation for mitosis of tumour and normal cells, it is still true that the wealth of information which has been collected during the past few years concerning the periodicity and length of DNA synthesis certainly permits some general statement.

(3) It is quite true that the *primum movens* of cell division must occur before, and not at the time of, initiation of DNA synthesis. The time of action and the nature of this *movens*, notwithstanding the elegant names and speculations of Prof. Bullough, are still completely unknown. Since we were concerned with what we were able to determine and measure, we chose the occurrence of certain biological events leading to the beginning of DNA synthesis as the time at which the decision to enter replication is irrevocably taken by a cell under normal conditions.

(4) Our communication was not intended to be a review, and the results in the table were selected with that in mind. Since results in numerous other publications dealing also with 'long generation time' cells have not contradicted our hypothesis, it seemed useless to list a long series of references. The case of the mouse skin was purposely omitted since there are conflicting reports on this 'complex situation' which cannot be resolved at the present time without the further work of interested workers.

DIURNAL FLUCTUATIONS IN THE NUMBERS OF DNA SYNTHESIZING NUCLEI IN VARIOUS MOUSE TISSUES

By C. PILGRIM, W. ERB and W. MAURER
Institut für Med. Isotopenforschung der Universität, Köln, Germany

IT has often been shown that the mitotic rates reveal marked diurnal fluctuations in various tissues of many organisms. In rats and mice the mitotic rates often seem to reach a maximum at night and a minimum during the day. Bullough has given two reviews of this subject and has discussed, in terms of waking and sleeping, the possible causes of these waves of activity[1,2].

This investigation was undertaken to discover whether the number of nuclei in DNA synthesis (S-phase) is also subject to diurnal fluctuations. Mice were injected intraperitoneally with tritiated thymidine (0·7 μc./g) at intervals throughout the day. Before and during the experiments the animals were kept under constant conditions and were fed *ad libitum*. Forty min after the injection the animals were killed by decapitation. Autoradiographs were prepared (Ilford $G5$ emulsion) from 3-μ thick paraffin sections of various tissues. Then the percentage of labelled nuclei (tritium index) and the percentage of cells in mitosis (mitotic index) were estimated. In addition, the mean grain number was counted in nuclei which had been cut approximately centrally. The results of one series of experiments are shown in Table 1. The figures are the average values from two animals, which showed little variation from the mean. In addition, the results were confirmed by a second series of experiments.

Table 1. TRITIUM INDEX, MITOTIC INDEX AND MEAN GRAIN COUNT PER NUCLEUS AT DIFFERENT TIMES OF DAY

Tissue	Hour of day	Tritium index (%)	Mitotic index (%)	Grains per nucleus
Œsophagus strat. bas.	5.30	1·5	0·83	9·2
	11.30	1·0	0·14	9·5
	17.30	6·4	0·19	9·7
	23.30	3·7	0·14	9·5
Fore-stomach strat. bas.	5.30	3·9	1·18	9·9
	11.30	3·0	0·38	9·5
	17.30	5·5	0·35	9·6
	23.30	3·8	0·42	9·6
Abdominal skin epidermis	5.30	1·7	0·47	9·1
	11.30	1·0	0·18	9·5
	17.30	4·5	0·21	8·9
	23.30	2·7	0·19	10·2
Tongue strat. bas	5.30	4·9	1·01	9·7
	11.30	4·3	0·17	9·9
	17.30	20·7	0·25	9·6
	23.30	9·9	0·59	9·6
Jejunum crypt. epith.	5.30	43	4·8	9·6
	11.30	42	4·7	9·2
	17.30	44	3·8	9·6
	23.30	41	4·7	9·8
Kidney convol. tub.	5.30	1·2	—	9·8
	11.30	1·2	—	9·9
	17.30	1·2	—	9·2
	23.30	1·1	—	9·1

It will be seen that no diurnal fluctuations in the mitotic index were present in the epithelia of the jejunal crypts. However, in the other epithelia of the digestive tract (tongue, œsophagus, forestomach) and in the abdominal epidermis diurnal fluctuations were obvious, a finding which agrees with the results of other authors[3]. It will also be seen that the tritium index shows similarly large fluctuations. Again, however, an exception is provided by the intestinal epithelium and also, in this case, by the tubuli contorti of the kidney. Thus, depending on the time of day, a partial synchronization is apparent in the S-phase nuclei precisely as can be seen in the mitoses.

The observed fluctuations in the tritium-index could be caused by diurnal fluctuations of the duration of DNA synthesis since an increase in the duration of DNA synthesis would result in an increase of the tritium index. However, according to Table 1, the mean grain number per nucleus does not show any diurnal fluctuation suggesting that the rate of synthesis, and therefore also the duration of synthesis, is constant. Thus the most probable explanation for the variations in the tritium index is that the number of nuclei entering S-phase from G_1-phase per unit time depends on the time of day.

From many of the papers previously published[2] the impression may be gained that the diurnal fluctuations in the mitotic index are directly due to parallel fluctuations in the triggering process of mitosis. In this case one would expect later on, during the following generation-cycle (that is, after the end of G_1-phase), to find a certain accumulation of S-phase nuclei. But it is very improbable that the observed fluctuations of the tritium index can be explained this way. For the rather sharp maximum of the tritium index would be difficult to understand since the G_1-phase requires several days in the cell types studied here and is certainly subject to additional individual variations. Furthermore, the fact that the time-interval between the tritium and the mitotic index is of similar size in all examined cell types would not fit into this theory.

It is much more likely that the primary process consists of a synchronization of S-phases. Consequently, one would expect an increase in the mitotic figures some hours later. The time-interval between the two maxima should be equal to = 1/2 S-phase + G_2 + 1/2 duration of mitosis. Unfortunately only incomplete data concerning the G_2-phase of the examined cell types are available. In the epithelia of the œsophagus and the forestomach (S-phase = about 8 h (ref. 4); G_2-phase = several h (ref. 5) the actually observed intervals of 12 h would be understandable in this way.

Furthermore, the experiments show (Table 1) that the duration of the period during which the mitotic index is at a maximum is approximately equal to the period during which the tritium index is at a maximum. (In some cell types the length of the mitotic index maximum might be somewhat shorter than that of the tritium index). In addition, the degree of fluctuation is about the same in both cases. This, too, is understandable if it is assumed that the length of the synchronization wave is approximately equal to the S-phase duration.

Equally great fluctuations of the tritium index were found in the ear epidermis. The interval between the maxima of the indices, however, was only a few hours (possibly plus any multiple of 24 h). These cells are also exceptional in that the duration of their S-phase is clearly longer than that in other tissues[6]. Further work on these cells might prove to be of special significance for the explanation of the phenomena of synchronization.

The experiments indicate that the causes of the fluctuation in the mitotic rate are obviously more complex than has been hitherto assumed. They can probably be interpreted, at least partially, as the result of a partial synchronization of S-phases.

In several publications the duration of the generation cycle has been deduced from the tritium index or from the mitotic index[7]. However, this is only possible in the case of a completely asynchronous cell population, that is when the cells are distributed uniformly throughout the different phases of the generation-cycle. The diurnal fluctuations in the number of cells in the S-phase described here show that this assumption may be unwarranted.

MOLECULAR GEOMETRY OF LANOSTENYL IODOACETATE

By JEAN M. OHRT and Dr. DORITA A. NORTON
Biophysics Department, Roswell Park Memorial Institute, Buffalo, New York

THE crystal structure of lanostenyl iodoacetate, $C_{32}H_{53}IO_2$ (Fig. 1), was determined by Fridrichsons and Mathieson in 1953[1] by use of 'heavy atom' single crystal X-ray diffraction analysis. The unit cell is orthorhombic (space group $P2_12_12_1$) with cell constants of $a_0 = 7{\cdot}6$ Å, $b_0 = 10{\cdot}9$ Å, and $c_0 = 38{\cdot}6$ Å, and contains four molecules. The density is 1·24–1·25 g/cm³. The atomic parameters obtained by Fridrichsons and Mathieson[1] have been used to calculate: (*a*) a series of 'best' plane equations for the entire molecule and various sub-portions thereof (Table 1) using the method of Schomaker *et al.*[2]; (*b*) the root mean square distances of atoms from the various 'best' planes (Table 2); (*c*) intra- and inter-ring dihedral angles (Table 3); (*d*) the perpendicular distances of individual atoms from one or more of the 'best' planes (Table 4). After consideration of these various calculations, the following details of the molecular geometry of lanostenyl iodoacetate are apparent:

(1) The 32 carbon atoms of the molecule have a non-planar spatial distribution. The 'best' plane passing through these atoms has the equation $0{\cdot}00x + 0{\cdot}85y + 0{\cdot}52z = 4{\cdot}68$. The root mean square distance of atoms from this plane is 0·75 Å.

(2) The steroid nucleus is also non-planar. The 'best' plane passing through the atoms of the steroid nucleus (C_1–C_{17}) has the equation $0{\cdot}04x + 0{\cdot}80y + 0{\cdot}60z = 5{\cdot}07$. (The coefficients of x, y and z are based on a Cartesian co-ordinate system in Å.) The root mean square distance in this case is 0·29 Å.

(3) Rings *A*, *B*, *C* and *D* have root mean square distances of 0·23, 0·24, 0·24 and 0·16 Å respectively and are non-planar, although ring *D* has a higher degree of planarity than rings *A*, *B* and *C*. The dihedral angles between the 'best' planes of these rings were calculated in order to visualize the overall trend of the lanostenyl iodoacetate molecule. It is apparent that *B* and *D* are nearly parallel, since $A \wedge B$ equals 162°, $B \wedge C$ equals 175°, and $C \wedge D$ equals 165°.

(4) The smaller sub-portions of the ring system are all planar, with the exception of *B*2 the atoms of which have

*O_2'																	

a root mean square distance of 0·17 Å. The atoms of the planar portions *A*2, *C*2 and *D*2 have root mean square distances of 0·01, 0·03 and 0·03 Å respectively.

(5) Combinations of the four-carbon-atom sub-divisions which have two common carbons are planar, namely, *A*3*B*1, *B*3*C*1 and *C*3*D*1, as can be seen from the root mean square distances of the relevant carbon atoms (0·01, 0·05 and 0·02 Å respectively). This planarity is also verified by the dihedral angles $A3 \wedge B1$ (177°), $B3 \wedge C1$ (172°), and $C3 \wedge D1$ (178°).

(6) The angular methyl groups C_{18} and C_{19} are at the same distance from the plane of the steroid nucleus (1·77 Å and 1·78 Å respectively).

(7) One of the two methyl groups attached to C_4, the C_{31} methyl, is bonded almost perpendicularly to the plane of the steroid nucleus as indicated by the near correspondence of the perpendicular distance of C_{31} from the plane of the steroid nucleus (1·49 Å) and the C_4–C_{31} bond-length (1·51 Å) (ref. 1). The other C_4 methyl group (C_{30}) is equatorial. Its perpendicular distance from the 'best' plane of the steroid nucleus is 0·54 Å, and its angular separation ($C_{30}C_4C_{31}$) from the C_{31} methyl group is 97°.

(8) The perpendicular distance of the methyl group (C_{32}) attached to C_{14} is 1·86 Å from the plane of the steroid nucleus. This approximately corresponds to the sum of the perpendicular distance of C_{14} from the 'best' plane of the steroid nucleus (0·27) plus the C_{14}–C_{32} bond length (1·54) (ref. 1), thereby indicating that the C_{32} angular methyl group is axial.

In conclusion, it may be said that the lanostenyl iodoacetate molecule is similar to the molecules of other steroids the molecular details of which have been worked out (namely, cholestery liodide[3,4], 4-bromoœstrone[5], and 4-bromoœstradiol[6]) in that neither the entire molecule, the steroid nucleus, nor the rings *A*, *B*, *C*, *D* are planar. The only exception to this is the instance wherein planarity of rings *A*, *B*, *C* and *D* is forced by the presence of three double bonds such as in the œstrogens. In all steroids thus far studied, true planarity is encountered only in sub-divisions of the molecule which are representative of the transjoined chair arrangement, that is, *A*1, *A*2, *A*3, etc.

We thank Miss Barbara Haner for assisting with the calculations.

STRUCTURE AND FUNCTION OF *E. COLI* ERGOSOMES

By DR. T. STAEHELIN, PROF. C. C. BRINTON*, jun., DR. F. O. WETTSTEIN† and PROF. H. NOLL*
Department of Microbiology, University of Pittsburgh

FROM our previous investigations on the structure and function of rat liver ergosomes[1–3] we concluded that protein synthesis requires the movement of messenger RNA (*m*RNA) through a series of ribosomal condensing sites at each of which the genetic message is transcribed nto the co-linear structure of a growing peptide chain. Thus, a cycle of protein synthesis is thought to begin with the successive attachment of 73 *S* ribosomes to one end of a messenger strand and to be terminated when these ribosomes have all been successively released at the other end, each of them with its finished polypeptide chain.

This 'tape-mechanism', that is the movement of *m*RNA through a ribosomal site in the synthesis of protein, appears to have been first advanced by Gilbert[4] and by Gierer[5]. Evidence for the idea that aggregates of several ribosomes, linked by one *m*RNA strand, are the functional units ('polysomes', 'ergosomes') was presented independently and almost simultaneously by Gierer[5], Warner, *et al.*[6,7] and Wettstein *et al*[1,2]. This interpretation

* Recipients of career development awards *GM-K*3-6312 (C. C. B.) and *GM-K*3-15, 274 (H. N.) from the U.S. Public Health Service.

implies that during the lifetime of a messenger RNA molecule *in vivo*, ribosomes are continuously attached and released so that the entire *m*RNA length is occupied by closely spaced ribosomes engaged in protein synthesis. Since *m*RNA is turning over *in vivo*, not all these ergosomes would be expected to be in a steady state in which an intact *m*RNA strand would be kept occupied by attachment and release of monomers, but some aggregates might be at any moment in a state of breakdown and others in process of assembly. Thus, the fraction of ergosomes present in the state of assembly and breakdown, and hence the size distribution of the ergosome population would depend on the average time required for assembly and breakdown relative to the average lifetime of *m*RNA. Since in this concept assembly and breakdown are coupled to protein synthesis by the movement of *m*RNA through the ribosomal condensing sites, we may estimate the proportion of ergosomes engaged in assembly and breakdown from the average number of protein molecules synthesized during the average lifetime of the messenger. In exponentially growing *E. coli*, a mean decay time of about 2 min has been estimated for *m*RNA (ref. 8) and a value of about 5 sec for the average time required to synthesize a polypeptide chain of 20,000 molecular weight[9]. Assuming an average ergosome size of $(70\ S)_7$, we calculate from these values that each *m*RNA molecule makes on the average about 100 polypeptide chains of mol. wt. 20,000. Hence the fraction of ergosomes engaged in assembly and breakdown should be small.

Contrary to this expectation, investigations with *E. coli* reported here indicate that bacterial extracts, even when prepared by particularly gentle disruption of the cells, contained predominantly 70 *S* monomers* and small oligomers. This might indicate that our isolation procedures resulted in the loss or breakdown of a substantial portion of the ergosomes. Nevertheless, by concentration methods which eliminate the bulk of the large population of small particles, it was possible to isolate ergosomes consisting of more than ten 70 *S* ribosomes. Examination of the structural features of bacterial ergosomes by sedimentation analysis and electronmicroscopy as well as studies on the kinetics of amino-acid incorporation *in vitro* gave results that are analogous to our previous findings with the rat liver system.

Preparation of ribosomes and soluble enzyme fraction. An unpiliated mutant of *E. coli* B_{am} (ref. 27) was grown with aeration in nutrient broth at 37° C to a density of approximately 5×10^8 bacteria per ml. and gathered by centrifugation after chilling with crushed ice. The cells were washed once with buffered salt solution (0·05 M hydrochloric acid–*tris* pH 7·6, 0·025 M potassium chloride, 0·01 M magnesium chloride and 0·005 M 2-mercaptoethanol) and disrupted by grinding for 10–15 min in a porcelain mortar with a mixture of powdered dry ice and glass beads. After the dry ice had evaporated, buffered salt solution was added to the paste (3 ml./g wet cells) and the suspension centrifuged at 18,000*g* for 10 min to remove unbroken cells and debris. The supernatant fluid (crude extract) was added in 5·5-ml. portions to 13-ml. centrifuge tubes that had been previously filled with 3·5 ml. of 0·5 M sucrose layered over 3 ml. of 2 M sucrose solution. The sucrose solutions were buffered by dissolving the required amount of sucrose in buffered salt solution. After centrifugation for 4 h at 40,000 r.p.m. and 0°–2° C in a Spinco model *L* ultracentrifuge, the upper 3·5–4 ml. of the supernatant fluid, which was free of ribosomal particles and DNA, was removed and kept frozen at −60° C. This fraction, designated 'post-ribosomal supernatant', contained the soluble enzymes and transfer RNA used for amino-acid incorporation *in vitro*. The interface between the 2 M and 0·5 M sucrose solutions which contained a gelatinous layer of DNA was discarded. The colourless translucent ribosomal pellet ('*C* ribosomes') was rapidly rinsed with 2 ml. buffered salt solution, resuspended to a concentration of about 3 mg RNA per ml. and stored at −60° C.

Zone centrifugation analysis. Centrifugation was carried out in a Spinco *SW* 25 rotor at temperatures close to 0° C as previously described[1,2,10]. The fluid was collected into an automatic fraction collector after passing through a continuous-flow ultra-violet absorption cell attached to a strip chart recorder. The fraction collector and strip chart recorder were synchronized with a precision pump which delivered the gradient fluid at a constant flow rate of 0·5 ml./min. Since the cylindrical absorption cell of 3-mm diameter gives a non-linear absorbance response, the recordings were corrected with the aid of a calibration curve and the scale was converted to read absorbancy units based on a 10 mm light path. The Mg^{++} concentration of the buffered salt solution used in the sucrose gradients was reduced to 0·005 M, in order to prevent the dimerization of free 70 *S* ribosomes observed at higher ratios of divalent to monovalent cations.

Amino-acid incorporation in vitro. The standard incorporation mixture contained the following reagents in μmoles per millilitre: hydrochoric acid–*tris* buffer *p*H 7·6 (50·0), magnesium chloride (8·6–9·0), ATP (1·0), GTP (0·4), potassium phosphoenolpyruvate (10·0), crystalline pyruvate kinase (10 μg), 2-mercaptoethanol (3·0). Ribosomes, post-ribosomal supernatant and ^{14}C-leucine were added as specified for each experiment.

For measurement of ^{14}C-leucine incorporated into protein, the samples were treated with perchloric acid, the precipitates collected on filter pads, washed and prepared for radioassay in a Packard liquid scintillation counter as described previously[1]. Counting efficiency was about 50 per cent.

Preparation of samples for electronmicroscopy. Purified ribosomes were prepared for electronmicroscopy at 0°–4° C by the collodion agar filtration method of Kellenberger[11], using agar which contained the same buffered salt solution concentration as the ribosomal solution. The filtered specimens were fixed with formaldehyde vapour for 7 min and the grids shadowed with 3/4-in. of 0·008-in. thick platinum wire at 41 amp for 40 sec at an angle of 4 : 1. The shadowed grids were examined with an R.C.A. electronmicroscope model *EMU–3F*.

Experimental Results. Representative sedimentation patterns of *E. coli* ribosomes, obtained after zone centrifugation of two different batches of crude extracts from exponentially growing cultures are reproduced in Fig. 1. In addition to the major proportion of 30 *S*, 50 *S* and 70 *S* particles, the presence of ergosomes is clearly revealed by a sequence of 4 distinct peaks corresponding to aggregates of the composition $(70\ S)_2$–$(70\ S)_5$, and by an unresolved band of even larger aggregates. Disregarding the 30 *S* and 50 *S* particles which might be nascent ribosomes, the aggregates accounted for about 18 per cent of the population of ribosomes and ribosomal aggregates (solid line) under the conditions used for disrupting the cells. This fraction was further increased to about 25 per cent when the cells were cooled as rapidly as possible to 0° C before gathering and extraction. Extracts from cells collected after slow cooling, on the other hand, were almost devoid of ergosomes.

For further investigations the ribosomes were purified by centrifugation through a double layer consisting of 0·5 M and 2·0 M sucrose solution. This procedure results in the selective concentration of aggregates, '*C* ribosomes'[1], as evident from the reduced proportion of 70 *S* monomers in the sedimentation patterns of the re-suspended pellets obtained from different crude extracts (Figs. 2*A*, 4*A*, 5*A*).

In subsequent experiments we obtained additional evidence that the bacterial ergosomes are closely analogous in their structural and functional properties to the mam-

* Following convention, we assign a 70 *S* value to the *E. coli* ribosome particle unit. To rat liver ribosomes we have assigned a value of 73 *S*. These values are not meant to reflect the true relative sedimentation rates of the particles from the two different sources.

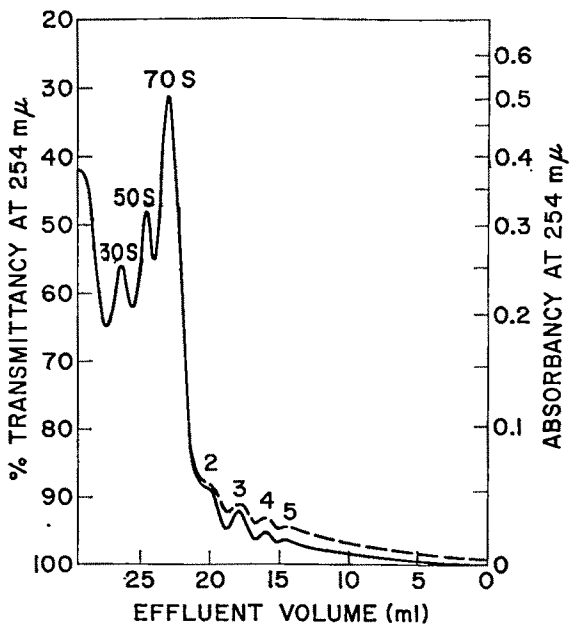

Fig. 1. Zone centrifugation of crude extract. Input corresponding to 0·5–0·6 mg RNA. Centrifugation for 3 h at 25,000 r.p.m. The solid and dashed lines represent two different extracts, normalized for equal input. The extract corresponding to the dashed line was prepared after more rapid chilling of the cells

malian ergosomes studied previously[1–3]. Thus, incubation of the bacterial ergosomes with traces of crystalline pancreatic ribonuclease (10^{-6} g/ml.) at 37° C for 5 min caused complete breakdown of the aggregates into 70 *S* monomers (Fig. 2*B*). A similar sensitivity to pancreatic RNase is exhibited by rat liver ergosomes which have been shown to break down by random cleavage of exposed *m*RNA bonds within aggregates[3]. Electronmicrographs of *E. coli* ergosomes show all the characteristic features first observed with ribosomal aggregates isolated from reticulocytes[6]. The preparations shown in the electronmicrographs in Fig. 3 were isolated from different regions of the sucrose gradient indicated in Fig. 4*A*, that is, from the monomer (*C*) and pentamer (70 *S*)$_5$ (*B*) peak, and from a cut in the unresolved region corresponding in position to aggregates ranging from (70 *S*)$_8$ to (70 *S*)$_{11}$ (*A*). General agreement of the aggregate sizes determined by sedimentation analysis or electronmicroscopy is evident from these data. In a number of aggregates, a filament-like structure, 10–20 Å thick, is visible, which appears to connect the ribosomal particles of 200–250 Å diameter (insert Fig. 3*A*). It seems reasonable to identify this structure with messenger RNA in view of other evidence supporting this conclusion[1–3,5–7,12–15].

In our previous work on rat liver ergosomes, we found that amino-acid incorporation *in vitro* is coupled to the successive release of single 73 *S* particles from the ribosomal aggregates engaged in protein synthesis. The evidence derived from a kinetic analysis of these two processes is compatible only with the tape mechanism of protein synthesis[3]. Several characteristic features of this mechanism are susceptible to experimental analysis by kinetic tests: (1) Each time the messenger has traversed a distance equal to the distance between two ribosomal condensing sites, the terminal 70 *S* particle is released from the aggregate together with a finished polypeptide chain. Thus, protein synthesis is accompanied by ergosome breakdown which proceeds through the stepwise release of monomers from one end of each aggregate. This can be tested experimentally by following in a sucrose gradient the breakdown pattern of an ergosome population resulting from protein synthesis. (2) The average amount of amino-acid incorporated per 70 *S* particle is proportional to the length of *m*RNA that, in the average, has passed through the condensing site of each ribosome. (*a*) If the time of protein synthesis is short, only a few amino-acids will be added to the growing end of the polypeptide chain present on each 70 *S* particle of an aggregate. Hence, if in a sucrose gradient we analyse a ribosome population of mixed aggregate sizes that had been exposed to a short incorporation pulse, the amount of radioactive amino-acid incorporated per unit of ribosomal mass should be independent of aggregate size. (*b*) If, on the other hand, ergosomes of different aggregate sizes are incubated separately for a long period until amino-acid incorporation ceases, the smaller ergosomes will have exhausted the stretch of *m*RNA available to them before the termination of the experiment, whereas the largest ergosomes will still be potentially active. The amount of radioactive amino-acid incorporated per unit of ribosomal mass should therefore be proportional to the initial aggregate size of each class of ergosomes, as with increasing aggregate size a proportionately longer piece of *m*RNA will in the average have passed through the ribosomal condensing sites. The following experiments were designed to test these predictions in the *E. coli* ribosome system.

The progressive breakdown of ergosomes in a population of mixed aggregate sizes (*C* ribosomes) during amino-acid incorporation *in vitro* is illustrated in Fig. 4, which shows the size distribution of *C* ribosomes in a sucrose gradient after incubation for 0 (*A*), 1 (*B*) and 6 (*C*) min. As already described previously[3], the increase in the absorbancy of the monomer peak indicates that the observed aggregate breakdown occurs through the stepwise release of 70 *S* particles as predicted by the tape mechanism. We have shown this pattern to be clearly distinguishable from that produced by random cleavage with pancreatic RNase[3].

The effect of short incorporation pulses on the distribution of nascent protein with respect to aggregate size was investigated in the same experiment. The distribution

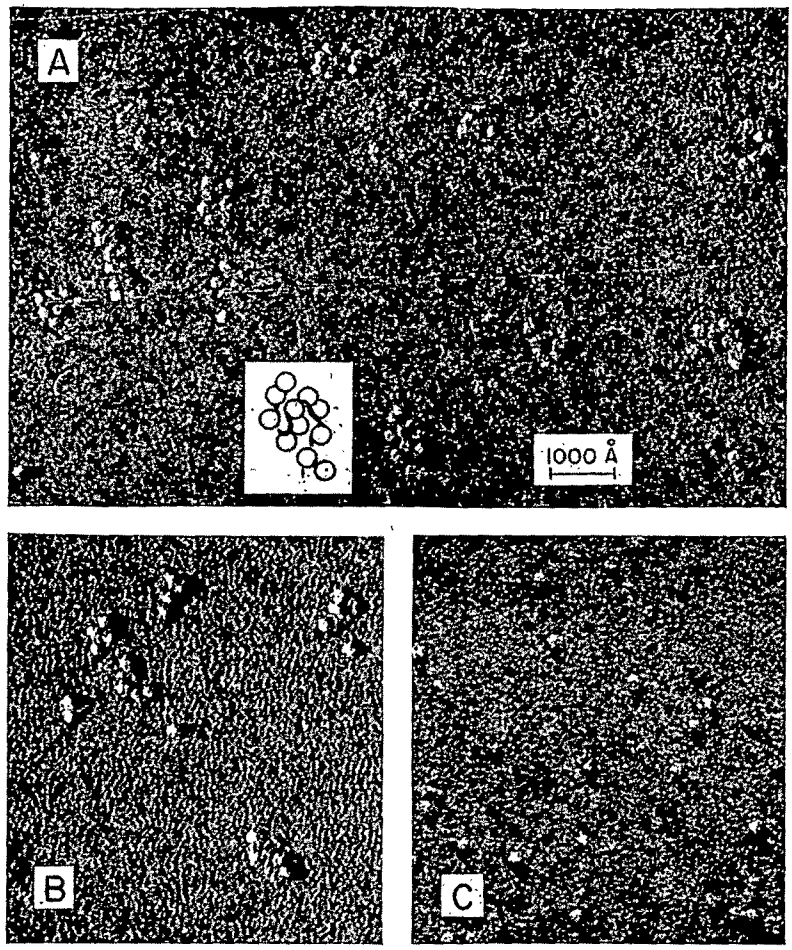

Fig. 3. Electronmicrographs of ribosomes isolated from different regions (*A*, *B*, *C*) of sucrose gradient shown in Fig. 4*A*. Insert in *A* shows enlarged drawing of the ergosome at right to suggest course of presumed *m*RNA-thread connecting eleven 70 *S* particles, as apparent on original plate

of labelled protein, synthesized during a 60 sec interval after addition of ^{14}C-leucine to the incorporation mixture, is shown in Fig. 4. In one sample the label was added at zero time (*B*), in another after 5 min of incorporation in the presence of ^{12}C-leucine (*C*). When the amount of labelled protein associated with different aggregate sizes was computed per unit of ribosomal mass, a constant value was obtained (Fig. 4, bottom graph). This indicates that the rate at which a polypeptide chain is synthesized at the condensing site of each 70 *S* particle in an aggregate is independent of aggregate size as expected from the tape mechanism. The radioactivity associated with the monomer peak is another manifestation of the breakdown process. For the monomers to which the labelled nascent protein is attached must originate from aggregates engaged in protein synthesis, since ribosomes in the monomer state are inactive, as shown in the subsequent experiment. In computing for different aggregate sizes the amount of radioactivity incorporated per absorbancy unit, a correction was made for the overlap of the monomer peak with the adjacent peaks of dimers $(70\ S)_2$ and trimers $(70\ S)_3$ as indicated by the dashed lines in Fig. 4. Fig. 4 also shows that, after 5 min of incubation, the incorporation rate has decreased to about 45 per cent of the initial value, indicating inactivation or depletion of rate-limiting enzymes or substrate components.

In order to test the postulated proportionality between aggregate size and the amount of protein synthesized per aggregate mass during long incorporation periods, *C* ribosomes were fractionated according to particle size by sedimentation in a sucrose gradient and later assayed for amino-acid incorporation during a 45-min incubation period. The sucrose gradient was cut into 29 1·0 ml. fractions, each of which was assayed separately. The sedimentation pattern, reflecting the size distribution of ribosomes before incubation, is reproduced in Fig 5*A* together with the distribution of the labelled protein that had been synthesized during the incorporation period. The results confirm our previous findings with rat liver ergosomes[1,3] and the results of Marks *et al.*[16] and of Gierer[5] with the reticulocyte system. The fractions containing mostly single 73 *S* particles were completely inactive. Moreover, the plot in Fig. 5*B* of specific activity (c.p.m. ^{14}C-leucine incorporated per 0·1 mg RNA) versus aggregate size shows a linear increase up to the heptamers $(73\ S)_7$; the curve then slopes off and reaches a maximum near $(73\ S)_{10}$. The apparent decline in the region of aggregates heavier than $(73\ S)_{10}$ might be due to contamination with unspecific aggregates or heavy cell components that had not been completely removed during the preceding centrifugations.

Discussion. The results of experiments on the structure and function of *E. coli* ribosomes described in this article support our previous conclusions, derived from studies of the rat liver system[3] that ribosomes become functional by attachment to *m*RNA and subsequent reading of the message by the tape mechanism as postulated by Gierer[5] and by Gilbert[4]. This process could explain the formation of ergosomes, the size of which would be determined both by the length and lifetime of *m*RNA, as previously discussed in detail[3].

Much recent debate has centred around the question of the nature of the active complex in *E. coli*, mainly because published data seem to conflict with respect to the *in vitro* incorporation activity of single 70 *S* monomers[17]. However, in the present concept these difficulties might be resolved by the following considerations. Available evidence suggests that a ribosome population obtained after breaking the cells contains at least four classes of potentially functional 70 *S* particles which reflect the different phases of ergosome assembly and breakdown.

(I) 'Vacant monomers'. These particles, which are released from ergosomes during protein synthesis *in vivo* and show a characteristic tendency for dimerization, make up the steady-state pool in the cell and are capable of accepting *m*RNA[2,4,5,18,19].

(II) Monomers to which a finished peptide chain is attached. This class of monomers accumulates during protein synthesis in cell-free systems that are limiting in release factor. On incubation with release factor, they are converted into class I monomers which are now competent to accept *m*RNA[5,20,21].

(III) Monomers containing both an unfinished peptide chain and a fragment of *m*RNA. These monomers result during the isolation procedures from cleavages by RNase of bonds within the exposed stretches of *m*RNA that connect the 70 *S* particles in ergosomes[1,5,7]. The piece of *m*RNA that remains attached to these monomers probably contains less than 50–60 nucleotides[3,19].

(IV) Monomers attached to the end of a nascent *m*RNA strand, a portion of which may still be combined with polymerase and the DNA template. It is tempting to speculate that such a hypothetical complex might represent the initial step in the assembly of ergosomes *in vivo*[3]. This complex would be expected to sediment faster than

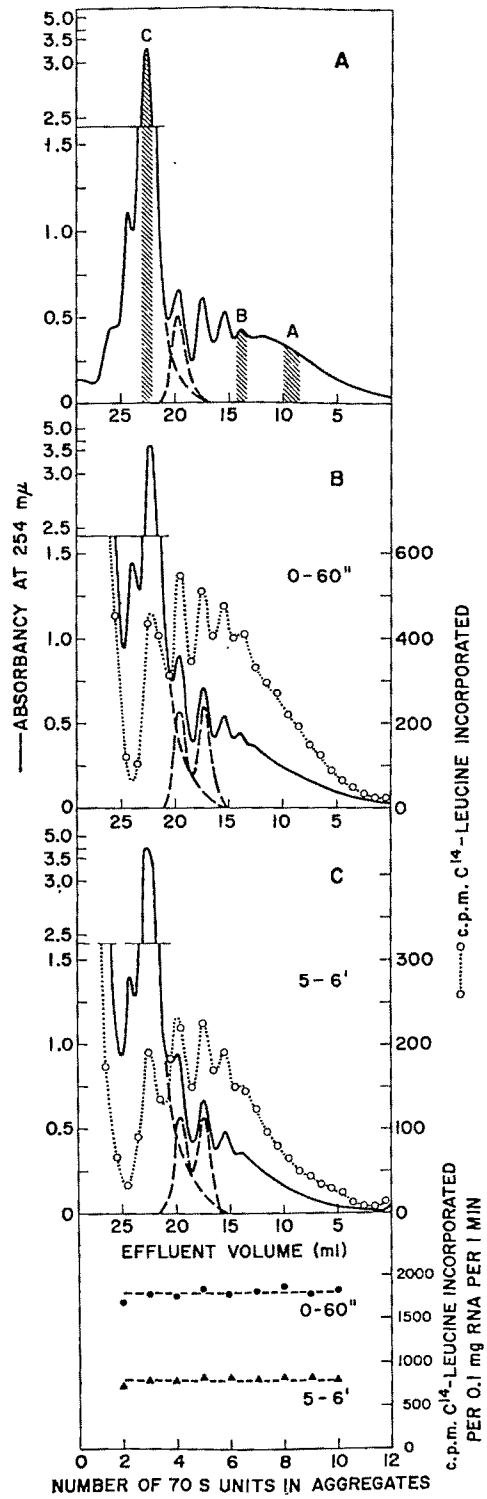

Fig. 4. Distribution of absorbancy and nascent protein associated with *C* ribosomes after incorporation pulses *in vitro*. (*A*) Sedimentation pattern of *C* ribosomes before incubation. (*B*) Sedimentation pattern of ribosomes and nascent protein labelled during 60-sec period at beginning of incubation period and (*C*) at end of 5-min incorporation in presence of non-radioactive amino-acids. The incubation mixtures (1·0 ml.) contained in addition to standard reagents: *C* ribosomes (0·8 mg RNA) post-ribosomal supernatant (0·3 ml.), and uniformly labelled ^{14}C-L-leucine (0·008 μmoles; 246 mc./mmole) which was added at zero time (*B*) or after 5 min (*C*). Reaction at 30° C was terminated by chilling, and mixtures centrifuged for 3 h at 25,000 r.p.m. The gradient fluid was collected in 1·0-ml. fractions and acid-insoluble material precipitated after adding 1·5 mg bovine albumin as carrier. The acid-insoluble radioactivity at top of gradient consists of *s*RNA-bound ^{14}C-leucine. The dashed lines show the absorbancies of the dimer and trimer peaks after correction for the estimated amount of contamination with monomers

the other classes of 70 *S* particles and might account for the active 'heavy 70 *S* ribosomes' sedimenting between 70 and 100 *S* (refs. 22, 23). The occurrence of such a complex could perhaps explain the origin of the large 12 *S* *m*RNA liberated from the 70–100 *S* region at low Mg^{++} concentrations[22].

In our experiments with purified ribosomes, and with an incorporation system from which most of the DNA, and hence the DNA-bound RNA polymerase[24], had been removed, the monomers were inactive. However, amino-acid incorporation by class III monomers expected to be present in this fraction cannot be ruled out, since the addition of only 1–2 leucine residues per growing peptide chain, permitted by the short *m*RNA piece of these particles, would have escaped detection. Monomers isolated from crude extracts, on the other hand, have been shown to synthesize protein, even in the presence of DNase[4]. This must be due to either the presence of class IV monomers or the attachment of class I monomers to *m*RNA generated by the polymerase reaction. This interpretation is supported by the findings of Doerfler *et al.*[24], who showed that the DNA–RNA–polymerase complex is relatively resistant to DNase and continues to function at DNase concentrations which cause rapid degradation of free DNA.

According to the tape mechanism, assembly of 70 *S* ribosomes into ergosomes is coupled to protein synthesis. The heavy complexes between 70 *S* ribosomes and poly U (refs. 4, 13–15, 17) or viral RNA (ref. 17), which may form in the cold and in the absence of the components required for protein synthesis, may result from fortuitous

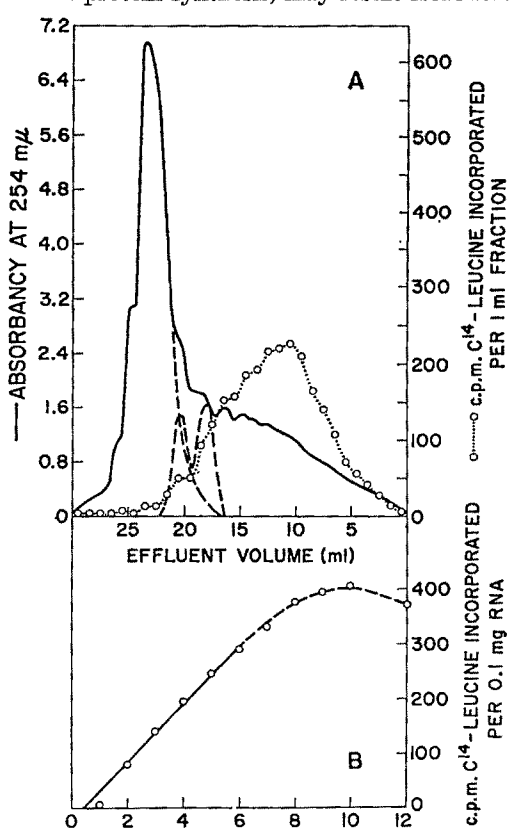

Fig. 5. Amount of protein synthesized after long incubation periods by fractions of different aggregate sizes. (*A*) Sedimentation pattern of *C* ribosomes (3 h at 25,000 r.p.m.; 3·2 mg RNA input) before incubation and total radioactivity incorporated as alkali-stable acid-insoluble counts during 45 min at 37° C by each 1·0-ml. fraction collected from gradient. (*B*) Specific activity (c.p.m. ^{14}C-leucine/0·1 mg RNA) as a function of aggregate size. The incubation mixtures (1·3 ml.) contained in addition to standard reagents: ribosomes (0·7 ml. from each gradient fraction), post-ribosomal supernatant (0·3 ml.), and DL-leucine-1-^{14}C (0·06 μmoles; 21·5 mc./mmole). *s*RNA-bound radioactivity was removed by incubating samples for 1 h at 25° C with 1 ml. 1 N sodium hydroxide before precipitation with acid

aggregation[17]. Thus, under ionic conditions which prohibit this secondary aggregation, Haselkorn *et al.*[17] found that at saturation about 10 per cent of their 70 *S* particles combined with about one virus RNA molecule in the cold and that the mixture synthesized protein on subsequent incubation in the complete system. Barondes and Nirenberg, on the other hand, observed that assembly of 70 *S* particles by TMV–RNA required conditions of protein synthesis[13]. Moreover, poly U-directed synthesis of polyphenylalanine usually proceeds with a characteristic lag, regardless of whether or not incorporation has been preceded by aggregation of ribosomes with poly U in the cold[13,25,26]. So long as in each of these experiments aggregation by fortuitous attachment of *m*RNA to ribosomes cannot be rigorously excluded, all these seemingly contradictory results in no way invalidate the view that the orderly assembly of 70 *S* ribosomes into functional ergosomes by sequential attachment of the particles to the cognate end of the messenger is coupled to protein synthesis.

GENETIC AND DEVELOPMENTAL STUDIES OF A QUANTITATIVE CHARACTER

By S. G. SPICKETT*
Department of Genetics, University of Cambridge

THODAY[1] has described techniques which can be used to locate some of the individual genes responsible for a heritable difference affecting a quantitative character. He pointed out that the location of such genes is a prerequisite to understanding their nature and their individual effects. This article describes the morphological effects of the components that have been isolated from such a polygenic complex.

The quantitative difference studied is that distinguishing the *Drosophila melanogaster* line vg 4 of Thoday and Boam[2] (which has a mean of about 37 chætæ) from the standard inbred wild-type strain Oregon (with a mean of about 20). The two differ at three loci[3,4] at each of which there are high chæta number factors in vg 4. Two high factors (III*a* and *b*) are at approximately 28·5 and 32·5 centimorgans in chromosome III, and the third (II) is at approximately 44 centimorgans in chromosome II. In the absence of II, III*a* and *b* have equal effects and they do not interact. II has only slight effect alone but II and III*a* interact, together increasing chæta number by more than the sum of their individual effects. There is no interaction between II and III*b*.

Regional effects of the different genes. The effects of these three genes on the arrangement of sternopleural chætæ were studied in a series of stocks differing at the three loci, much of the rest of their genomes being derived from inbred Oregon. A cavity slide was prepared which made it possible to orientate the flies in a standard way so that they might be drawn with the aid of an Abbé *camera lucida*. The sternopleurites were drawn and the positions of all the chætæ noted. The drawings were then scanned with a grid which divided the sternopleurite into several regions as illustrated in Fig. 1.

Drawings were made of both sides of 50 male and 50 female flies in each of the stocks. Statistical analyses of the frequency of chætæ in the different regions (details of which will be given in a fuller publication) show that there are no significant differences between sexes or between sides, but there are differences between genotypes. The chæta numbers in each region for each genotype are given in Table 1, and the increases (compared with Oregon) are given in Table 2.

It can be seen that III*a* increases chætæ in all parts of the sternopleurite though in region *A* the effect is slight and not demonstrably significant. The other factors appear to exert more local effects. III*a* also increases the number of chætæ on other parts of the fly (Table 3) whereas III*b* and II do not. III*a* therefore has a general effect on the number of chætæ that the flies bear, although region *A* is not affected so much as the other regions are.

Both this evidence that III*a* has a general effect, whereas that of III*b* is local, and that they differ in their

IIIa+ IIIb+ II / IIIa+ IIIb+ II	212	474	288	1,204	2,173
IIIa IIIb II+ / IIIa IIIb II+	220	366	363	1,713	2,692
IIIa IIIb+ II / IIIa IIIb+ II	228	762	350	1,412	2,752
IIIa+ IIIb II / IIIa+ IIIb II	214	498	295	1,515	2,522
IIIa IIIb II / IIIa IIIb II	228	746	355	1,718	3,047

Table 2. Percentage Increase in Chætæ in Each Region compared with Oregon Inbred

Genotype	A	B	C	D
IIIa IIIb+ II+ / IIIa IIIb+ II+	9·8	16·5	19·9	17·5
IIIa+ IIIb II+ / IIIa+ IIIb II+	2·0	10·7	7·0	26·7
IIIa+ IIIb+ II / IIIa+ IIIb+ II	3·9	47·2	−1·0	00·6
IIIa IIIb II+ / IIIa IIIb II+	7·8	13·7	26·9	43·1
IIIa IIIb+ II / IIIa IIIb+ II	11·8	136·6	22·4	18·0
IIIa+ IIIb II / IIIa+ IIIb II	4·9	54·7	3·1	26·6
IIIa IIIb II / IIIa IIIb II	11·8	131·7	24·1	43·5

Table 3. Mean Chæta Numbers in Various Parts of IIIa and Oregon Flies

Area	Genotype IIIa	Oregon	Significance level of differences
Sternopleurite	30·6	19·8	$p<0·001$
Coxæ first pair of legs	26·6	22·4	$p<0·001$
Coxæ second pair of legs	29·6	23·4	$p<0·001$
Fourth and fifth abdominal sternites	45	41	$p<0·001$

interactions with II, show that the linked pair of polygenes on chromosome III function in quite different ways, though their effects on total sternopleural chæta number are quantitatively equal and additive. The interaction between IIIa and II is also localized.

Size of fly and number of chætæ. It is known that number of chætæ is sometimes correlated with size of fly[5] and it was expected that IIIa, as its effect is general, would prove to increase the size of the fly. Flies with IIIa and that section of the vg 4 chromosome III to the left of IIIa were therefore weighed, but there was no difference in weight distinguishing them from Oregon. However, further genetic analysis has shown that this is because there is in the vg 4 chromosome an additional factor that decreases fly size without affecting chæta number.

The method of chromosome analysis of the left arm of chromosome III is described by Thoday, Gibson and Spickett[3] and need not be detailed here. The technique (which is derived from that of Breese and Mather[6]) makes it possible to build up chromosomes of which a known part comes from the stock under test, the remainder coming from Oregon. The marker stock *ve, h, eyg, cp* was used to make such 'synthetic' chromosomes. If the left arm of chromosome III or Oregon is represented as L L L L, each L being that part of the chromosome in the region of a marker, the left arm of vg 4 may be similarly designated H H H H. Using this notation we may, for example, designate as L L H H the various types of synthetic chromosome combining *ve* and *h* regions from Oregon with the *eyg* and *cp* regions from vg 4. The probability that a factor, located between *h* and *eyg* and which distinguishes vg 4 from Oregon, will be found in the L L H H chromosome will depend on its position on the linkage map between *h* and *eyg*. The results obtained by weighing flies from several stocks of each type of 'synthetic' chromosome are shown in Fig. 2. It is clear that there are in vg 4 a weight diminishing factor (designated IIIw) to the left of the locus *h* (it is at about 13 cM) and a weight-increasing factor between the loci *h* and *eyg* (which is at about 29 cM, that is, very close to, if not at, the same locus as IIIa). In addition, all the H H L L stocks containing IIIa that were derived by Thoday, Gibson and Spickett[3] were similar in weight to Oregon, but those without IIIa were lighter than Oregon. Their L L H H stocks were also of two weight classes. Those which carry IIIa are heavier than Oregon. Those that do not carry IIIa are lighter than Oregon. The presence or absence of IIIb had no detected effect on weight. There is therefore considerable evidence in favour of the chæta increasing factor IIIa and the weight increasing factor being very closely linked if not the same. At least in the experiments reported here they were inherited as one.

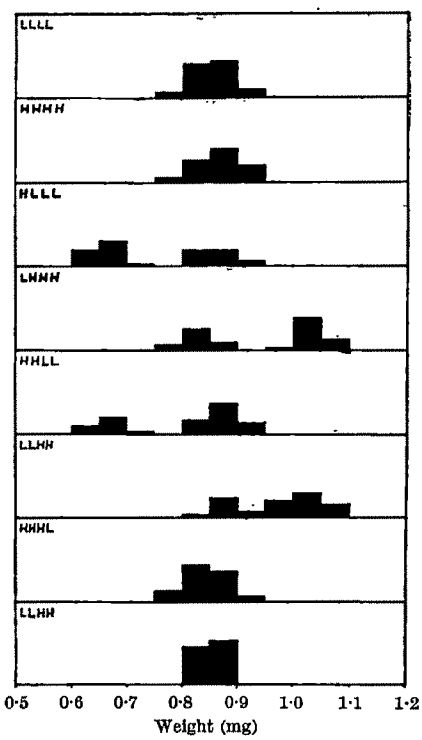

Fig. 2. Chromosome analysis of vg 4 for factors affecting fly weight. Data based on thirty stocks of each type of synthetic chromosome. Twenty male flies were weighed from each stock

As the locus IIIw has no effect on sternopleural chæta number whereas IIIa affects both weight and chæta number, it is clear that different polygenic systems affecting different characters may have loci in common. The situation provides an example of the type of complex discussed by Mather[7] and demonstrated by Breese and Mather[8] which involves interlocking of different polygenic systems.

Size and number of cells. Following this demonstration that the different chæta number loci have different morphological effects, attention was concentrated on variation in the hypodermis of the sternopleurite as the larger flies tend to have larger sternopleural areas[5]. The hypodermis was removed from the sternopleural region, rapidly stained in hæmatoxylin and mounted in water under a coverslip. All the nuclei in a standard area were counted and drawn with the aid of a *camera lucida* using standard magnification. This was done for stocks carrying IIIa and for stocks carrying IIIw (both on Oregon backgrounds) and for Oregon itself. The results (Table 4) show that IIIw flies have more nuclei in the standard area

Table 4. Number of Nuclei in a Standard Field, Relative Area of Sternopleurite and Ratio of Proportionate Cell Numbers in Sternopleural Hypodermis

	Genotype		
	Oregon	III*a*	III*w*
No. of nuclei in a standard field (x_n)	449	462	518
Relative sternopleural area (y_n)	86	98	79
Ratio of proportionate cell Nos. in sternopleural hypodermis $\frac{x_n}{x_{Or}} \times \frac{y_n}{y_{Or}}$	1·00	1·17	1·06

than III*a* or Oregon and they therefore have smaller cells. At the same time III*w* has a smaller sternopleurite area than Oregon, and III*a* a larger area than Oregon. Estimates from these data of the relative number of cells in the sternopleurite show that III*w* and Oregon have similar numbers of cells whereas III*a* flies have more cells.

Wigglesworth[9,10] has shown that in *Rhodnius prolixus* body size may be altered either by changing cell number or by changing cell size, and that variation in cell size does not affect the number of epidermal plaques that develop whereas variation in cell number does. The present results suggest that the same is true of *Drosophila melanogaster*, for III*w*, which affects cell size, does not seem to influence the differentiation pattern whereas III*a*, which increases cell number, generally increases chæta number.

*Local effects of II and III*b. In considering the local effects of the other two genes (II and III*b*) we have to take into account the development of chætæ in *Drosophila melanogaster*, which has been described by Lees and Waddington[11]. During its development, the chæta initial cell undergoes a transient but considerable enlargement. Such cells in this condition are easy to see in the sternopleural hypodermis if it is stripped, during the white puparium stage, and viewed from the inner side after brushing with indian ink. In low chæta number flies and in all flies examined, except those carrying II, the earliest enlarged cells were in positions similar to those of the three large chætæ *a*, *b*, *c* (see Fig. 1). The other large cells develop later. However, in flies carrying II only two large cells were seen in the younger hypodermis, in positions *a* and *c*; later several large cells develop in the region of *b*, which is, in such flies, occupied by several smaller chætæ. It may therefore be concluded that large chætæ develop earlier than small chætæ and that II brings about its effect by delaying the initiation of chætæ in region *B*.

No differences in region *D* were observed in the time of chæta initiation. However, measurements of the chætæ showed that they were shorter in flies with III*b* than in other flies. Moreover, chætæ were found over a relatively larger area in III*b* flies and this found expression in the tendency to form a second row of chætæ in region *D* (Fig. 3).

Conclusions. The activities of the factors may be summarized as follows:

III*a*. Increases the size of the fly by increasing cell number, and as a consequence produces a general increase in chæta number.

III*b*. Increases the number of chætæ in region *D*, extending their distribution and reducing their size.

II. Retards the development of large chætæ in region *B* with the result that several smaller chætæ develop in this region.

III*w*. Decreases fly size by reducing cell size and in consequence compensates for the size effect of III*a* without altering III*a*'s effect on chæta number.

This knowledge makes it possible to propose a model for the development of chæta pattern in the sternopleurite.

Stern[12] has argued that, in *Drosophila melanogaster*, there are regions or 'pre-patterns' within the bounds of which any competent tissue may form chætæ. Such a pre-pattern may be the expression of the distribution of some substance essential to the development of chætæ from hypodermal cells. The competence of the hypodermal cells may depend on another substance. Variation in chæta pattern could be caused by changes in the overall distribution and concentrations of either of these two substances. The peaks of concentration in regions *A*, *B* and *C* must be both high and sharp so that a single cell starts to differentiate well in advance of the others and hence takes up essential substrates to such an extent that it excludes the possibility of differentiation of other chætæ near to it. These peaks may be lowered or dispersed by the action of a gene (for example, II in region *B*) so that no single cell shows precocious differentiation but instead several cells start to differentiate at the same time and several smaller chætæ develop instead of one large chæta. If the number of cells in the element is increased the intensity of suppression of new differentiation between two differentiating centres would diminish. Thus the effect of II in causing later, but more frequent, differentiation centres between *a* and *b* is enhanced by III*a*, which causes more cells to intervene between *a* and *b*. Redistribution of the pre-pattern over a larger area would result in the formation of more chætæ, but if the amount of chæta differentiating substrates were the same the chætæ would be smaller. This appears to be the effect of III*b*.

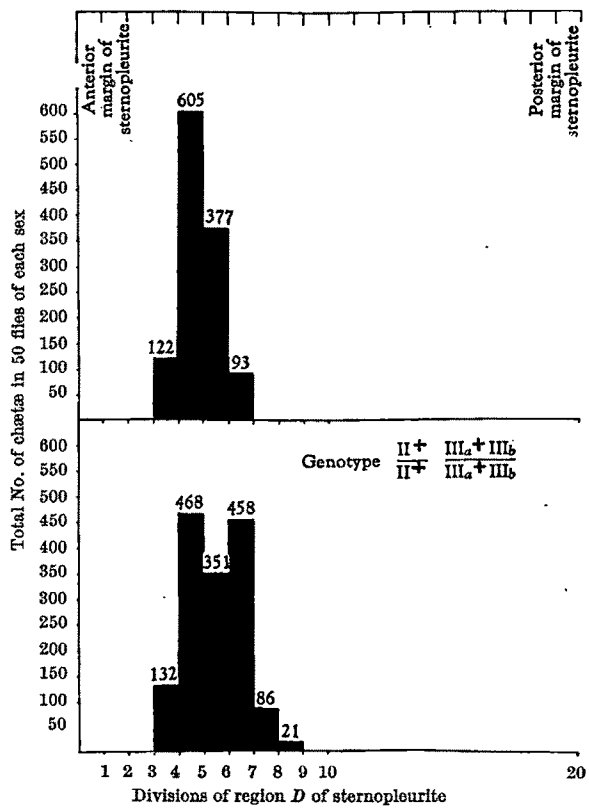

Fig. 3. Distribution of chætæ in region *D* of sternopleurite of Oregon and III*b* flies. The region was divided into twenty sectors from anterior to the posterior margin and the number of chætæ in each sector of fifty flies of each sex of each kind is plotted in the figure

That different parts of a single pattern may be separately affected by genetic variation as has been shown previously by Smith and Sondhi[13], and Reeve[14] has shown that the sternopleural chæta pattern of *Drosophila melanogaster* may be changed specifically by selection. The present report shows how such observations may be extended when the different genes can be handled more precisely in breeding experiments, and also shows how the separate effects of individual polygenes (which in this example are quite different) may then be investigated, in a way similar to that which has been used by previous workers, for example, Waddington[15], who studied the effect of major gene differences with the view of aiding understanding of development.

IMMUNOLOGICAL COMPETENCE OF THYMUS CELLS AFTER TRANSFER TO THYMECTOMIZED RECIPIENTS

By R. B. TAYLOR
National Institute for Medical Research, Mill Hill, London, N.W.7

THERE is now much evidence that the thymus controls the origin and multiplication of lymphocytes and the development of the immune response. In embryonic life the lymphocytes of both thymus and spleen arise only from the thymic epithelium[1]. After birth, the presence of the thymus is necessary for the development of the lymphoid tissues and of immunological responsiveness[2]. In the adult it is required for the recovery of responsiveness after irradiation[3,12]. The means by which the thymus influences lymphopoiesis is still in doubt. In neonatally thymectomized mice grafted at one week of age with cytologically marked neonatal thymus, Miller[5] found that by the time the mice had reached adulthood, responsiveness had been restored, and donor mitoses were present in the spleen. This observation gave substance to the hypothesis, proposed by many authors, that the thymus is the source of lymphocytes, and that during development these are 'seeded out' to the other lymphoid tissues, and become the competent cells of the adult. Further investigations showed that the thymus graft itself becomes largely re-colonized by host cells, while results obtained with the use of Simonsen's discriminant assay revealed that the cells responsible for competence in the spleen were mainly of host origin[16]. This suggested that some type of cell (perhaps of thymic origin in the first place[1]) may enter the thymus, divide therein, and then pass out to the other lymphoid tissues. There is evidence that this cell resides principally in the bone marrow[4,18].

The cell responsible for competence is probably a small lymphocyte[7]. In view of this, and the foregoing evidence that some competent cells come from the thymus, it is of interest that the thymus itself, which consists largely of lymphocytes, does not respond to most antigenic stimulations[8]. Moreover, suspensions of thymus cells have only a very low ability to transfer secondary responsiveness to protein antigens[9], and their performance in the graft-versus-host reaction is poor[10]. Evidence summarized here shows that thymus cells are nevertheless capable of acquiring a degree of competence comparable with that of lymph node cells.

The aim of the experiment (Fig. 1) was to test the ability of various lymphoid tissue inocula to restore responsiveness to thymectomized mice, and then to determine what proportion of the competent cells had been provided by these inocula. *CBA* mice were thymectomized at 2–3 days old. Thymectomy at this age in *CBA* mice leads to a mild form of wasting disease, but rarely results in the premature death seen after thymectomy earlier in life[5,6]. However, it greatly depresses the capacity of *CBA* mice to produce antibody against bovine serum albumin (BSA) and impairs to some extent the ability of their lymphoid cells to cause a graft-versus-host reaction in F_1 hybrid hosts[12]. Thirty male mice were thymectomized and six sham-operated. Seven weeks later the thymectomized mice were divided into 5 groups of 6 and were treated with various lymphoid tissue inocula as detailed in Table 1. The donors were of both sexes and were aged either 2–3 days ('neonatal') or 2–3 months ('adult'). Three of the transfers in each group were taken from mice co-isogenic with *CBA* but bearing the T6 marker chromosome (*CBA/T6*), and the other three from normal *CBA* mice. After a further seven weeks the mice were injected with BSA in Freund's adjuvant[13], and then bled 35 days later. The titres of antibody in the sera were measured by Farr's antigen-binding-capacity method[14].

* Standard deviations.
† In the thymus graft of this mouse 17/17 mitoses were of host origin.
NR, no result due to death or other accident.

An attempt was then made to estimate, by chromosome analysis, the proportion of donor-type cells among the competent cells of the mice which had received grafts or cell transfers from the *CBA/T6* donors. Each experimental mouse was killed and a cell suspension made from its lymph nodes. This was injected intravenously into a lethally irradiated (1,000 r.) (*C57BL*) × *CBA*)F_1 mouse. Two to three days later the hybrid recipient was injected with 4 μg/g body-weight of 'Colcemid' (Ciba) and chromosome preparations were made from its lymph nodes

(mod. of 15). A chromosome analysis (without cell transfer) was also made on one of the neonatal thymus grafts, after exposure to 'Colcemid' *in vitro*. The proportion of mitoses in normal lymphoid tissues which belong to immunologically competent cells is unknown, and may be quite small. The purpose of the foregoing procedure was to amplify this proportion. A reconstruction experiment[12] has indicated that the majority of mitoses in the irradiated hybrid recipients probably represent donor cells engaged in a graft-versus-host reaction. Thus the proportions of *T*6 mitoses recorded in Table 1 reflect the proportions of cells, among those competent to react to *C57BL* antigens, which had arisen from the original *CBA/T*6 inocula.

The remaining mice in the thymectomized groups (I–V) were used in graft-versus-host assays. In these the potency of lymphoid cell suspensions (spleen and lymph nodes) from the thymectomized mice in causing spleen enlargement in $(C57BL \times CBA)F_1$ recipients was compared with that of the sham-operated controls. A standard 4-point assay procedure was used. For details of this see ref. 17. The potency was then multiplied by the factor:

$$\frac{\text{No. of cells in thymectomized mouse}}{\text{No. of cells in sham-operated mouse}}$$

to obtain the 'responsiveness' of the thymectomized mouse relative to the sham-operated control. Referring to Table 1, Groups I and II, it can be seen that adult thymus cells had been as effective as lymph node cells in the restoration of responsiveness to BSA, and that both had provided a substantial proportion of the cells competent to perform a graft-versus-host reaction.

Antibody production in the thymus may normally be prevented by the existence of a blood-thymus barrier which is impermeable to antigens, as suggested by Marshall and White[11]; but this does not explain the low activity of thymus cells in the graft-versus-host reaction[10,12]. In this situation, however, they are of necessity exposed to antigen immediately after transfer, whereas in the experiment just described a period of 7 weeks was allowed to elapse between cell-transfer and antigenic stimulation. Further experiments have since shown that the competence of thymus cells remains low even up to 1 week after release from the gland, but is well developed by 6 weeks[12]. Presumably these cells require to undergo some process of maturation before they can become competent. The results obtained with the mice which received thymus grafts (Groups II and IV of Table 1) confirm those of Miller[16] mentioned in the introductory paragraph, while using chromosome analysis rather than Simonsen's discriminant assay to determine the origin of the competent cells. It can be seen that by the time of challenge with BSA, responsiveness to this antigen had been restored in the mice receiving neonatal thymus grafts, but not in those receiving adult thymus grafts. However, by the time the graft-versus-host assays were made Group IV had also acquired responsiveness—at least to tissue antigens—and indeed the graft-versus-host responsiveness in both Groups III and IV was higher than in Group 1. The results of the graft-versus-host assays were also borne out in the chromosome analyses by observation of the mitotic density. Although no measurements were made, this was obviously higher in Groups III and IV than it was in Groups I and II. Thus, while being at least equal in competence to Groups I and II, the mice receiving thymus grafts show, among their competent cells, a smaller proportion of donor origin, as can be seen from the chromosome analyses. It is therefore evident that, besides providing competent donor cells, the thymus grafts had caused an increase in the number of competent host cells. While it seems very probable that the grafts brought about this result partly by stimulating host-cell division within themselves, they might also have stimulated lymphopoiesis in other sites by humoral means.

This work was done while I was in receipt of a Wellcome fellowship from the Animal Health Trust.

DORMANCY REGULATORS IN WOODY PLANTS

Experimental Induction of Dormancy in *Betula pubescens*

HEMBERG[1] first proposed the theory that growth-inhibiting substances play a part in the regulation of bud dormancy in woody plants. The theory is mainly supported by the fact that a correlation can be shown to exist between seasonal changes in the state of dormancy of the buds of certain species and corresponding variations in the levels of the endogenous inhibitors within them. Thus, it has been shown for several woody species that the gradual reduction of bud dormancy during the winter is associated with a decrease in the level of endogenous growth-inhibitors[1–5]. Moreover, it has been shown that short-day conditions, which induce dormancy of woody plants, result in increased levels of inhibitors in the leaves and buds[6–8]. The inhibitory effect on the growth of buds exerted by leaves maintained under short-day conditions strongly suggests the transmission of inhibitory substances from the leaves to the buds[9,10]. Nevertheless, the crucial test of whether dormancy can be induced in actively growing seedlings of woody plants by application of inhibitors extracted from the same species has apparently not been carried out; the present report describes the successful induction of dormancy in seedlings of *Betula pubescens* by such treatment.

The inhibitor solution for these experiments was obtained from the leaves of *Betula pubescens* by extraction with 80 per cent aqueous methanol, and subsequent partition into ether. The ether fraction was further partitioned by paper chromatography with isopropanol/aqueous ammonia (sp. gr. 0·880 × 1/100) (4:1 v/v) as solvent, and the zone at R_F 0·65–0·95 was eluted in water and reduced to a convenient volume. In preliminary experiments it was found that the inhibitor significantly reduced the hypocotyl extension of birch seedlings grown on it. Since the inhibitor was obtained from the leaves, it seemed reasonable to re-apply it to the leaves. The inhibitor solution was applied to the leaves of actively growing birch plants maintained under a 14·5-h photoperiod, by immersing a leaf of each plant in an aqueous solution of the inhibitor contained in a small tube. The solution was renewed regularly during the experiment which lasted

28 days. Measurements of stem extension were recorded, and it was clear that the water-treated control plants were growing actively throughout the experiment, whereas the apical growth of the inhibitor-treated plants was completely arrested.

The compact structure of the arrested apices was in marked contrast to that of the actively growing apices and in this respect closely resembled the apices of plants rendered dormant by short-days. These results suggested that the inhibitor had induced a state of dormancy, a conclusion that gained further support from the results of extractions of the arrested and actively growing apices. Higher levels of the inhibitor were detected in the apices of the inhibitor-treated plants as determined by the coleoptile-section test. The possibility remained that this condition may have arisen by the action of a toxic substance. This possibility was tested in a subsequent experiment where the plants were treated with the inhibitor solution for 28 days, by which time the apical growth was arrested, and then gibberellic acid was applied to the buds. The buds rapidly expanded and the resulting growth showed no evidence of toxicity or abnormality. These results would seem to provide strong evidence in support of the inhibitor hypothesis of dormancy.

On the other hand, the discovery that gibberellic acid overcomes the dormancy of many tree buds raises the question as to whether endogenous gibberellins are also involved in the regulation of dormancy. It has been mentioned that the resting-buds formed in response to applied inhibitor readily resumed growth, indicating that gibberellic acid can overcome the effect of the inhibitor. This conclusion was supported by the results of an experiment in which shoots of birch, collected in mid-March, were placed with the basal end in inhibitor solution in conjunction with various concentrations of gibberellic acid. Bud-break was greatly reduced in the presence of inhibitor, but at gibberellic acid concentrations of greater than 1 mg/l. the effect of the inhibitor was overcome. Thus, the effect of winter-chilling in overcoming the dormancy of buds may be due to an increase in the levels of endogenous gibberellins rather than to a reduction in the inhibitors. This hypothesis is suggested by observations on potato tubers[11] and hazel seeds[12], in which an increase in endogenous gibberellins occurred in response to chilling. Further evidence is provided by our own observations that there are significant changes in the levels of endogenous gibberellins in the buds of *Acer pseudoplatanus* during December–April, certain fractions increasing and others decreasing during this period. Thus, the emergence of buds from dormancy may be regulated by a balance between growth-inhibitors and endogenous gibberellins.

It is clear that a large number of substances occurring in plant-tissues are likely to be inhibitory to growth, but the existence of growth-inhibitory activity does not, in itself, indicate that such substances are important in dormancy. However, the demonstration that the growth-inhibiting fraction extracted from birch leaves can induce dormancy in seedlings of that species strongly suggests the existence of endogenous dormancy-regulating substances, and it is proposed that the term 'dormin' should be used for substances which appear to function as endogenous dormancy-inducers.

Isolation of the Inhibitor varying with Photoperiod in *Acer pseudoplatanus*

Seedlings of *Acer pseudoplatanus* show marked photoperiodic responses in relation to dormancy[1]. Under short days the seedlings rapidly cease extension-growth and form resting-buds, whereas under long days extension-growth is more prolonged. The possibility that the dormancy of buds and other resting-organs results from the presence of specific growth-inhibitors[2] suggests that the induction of dormancy by short days may be due to the greater production of inhibitors under these conditions as compared with long days. Evidence in support of this hypothesis was obtained by Phillips and Wareing[3], who found that transfer of *A. pseudoplatanus* from long-day to short-day conditions resulted in greater production of a substance which inhibited extension-growth in sections of wheat coleoptiles. Further work to isolate and determine the chemical nature of these growth-inhibitory fractions in *A. pseudoplatanus* is now described. For the work described in this paper, growth activity was assayed by the 'straight-growth' method with 1 cm sections of wheat coleoptiles, but it is significant that the substance was also effective as an inhibitor of elongation in sections of hypocotyls from *A. pseudoplatanus* and inhibited expansion of leaf disks cut from this species. When extracts of *A. pseudoplatanus* were chromatographed on paper with isopropanol/aqueous ammonia/water as solvent the inhibitor was detected at R_F 0·6–0·8, corresponding to the location of the 'inhibitor β' of other workers.

Large batches of leaves from *A. pseudoplatanus* have been extracted in order to identify the inhibitor which is varying with photoperiod. The leaves were extracted with aqueous methanol (80 per cent v/v) and after removal of the methanol by vacuum distillation the aqueous extract was shaken with diethyl ether. The ether phase was separated into acid and neutral fractions and the acid fraction, which contained the inhibitor, was chromatographed on paper with isopropanol/aqueous ammonia (sp. gr. 0·880)/water (10:1:1 v/v/v) as solvent. The inhibitor was located at R_F 0·6–0·8 and the eluate was re-chromatographed on paper with *n*-butanol/aqueous ammonia (sp. gr. 0·880 × 1/100) in the proportion 5:1 (v/v) as solvent. The inhibitor ran at R_F 0·4–0·6 and was separated from several non-inhibitory phenolic compounds which ran at the same R_F as the inhibitor in isopropanol/aqueous ammonia/water.

The inhibitor was eluted from the chromatograms, developed with *n*-butanol/aqueous ammonia and reduced in volume until dry. The residue was distributed between ether and 0·1 M sodium phosphate buffer (*p*H 5·8) for 50 transfers in a Craig apparatus. Material in the aqueous layers was recovered by extraction into ether after acidification to *p*H 3. On bioassay, one fraction completely inhibited extension-growth of coleoptile sections when assayed at 50 p.p.m. and in this respect was as active as coumarin. This fraction was non-crystalline, colourless and had a distinctive odour. Ultra-violet and infra-red examinations of the fraction indicated the presence of —OH, —CO—, —CH_2— and/or —CH_3 groups, but there was no evidence of an aromatic structure. The fraction formed a precipitate when added to 2,4-dinitrophenylhydrazine in 2N-hydrochloric acid and showed some reducing power towards hot Fehling's solution. The inhibitor was found to be unstable to acid, alkali and heat at 100° C. Biological activity was also destroyed by treatment with sodium borohydride but not by treatment with sodium periodate. Thus, there is strong evidence for the presence of an aldehyde or ketone group in the inhibitor, which could possibly be a β-hydroxy acid.

Thus it appears that inhibitor β in *A. pseudoplatanus* could be a single active compound and not an accumulation of several weakly inhibitory substances which have similar R_F values, as has been found in some other species.

Also, the fact that the inhibitor does not appear to be an aromatic compound conflicts with the suggested nature of inhibitor β in several other species of plants and plant organs. Varga[4] has extracted growth-inhibitors from several species of fleshy fruits and concludes that inhibitor β is composed of several aromatic compounds and, in particular, phenolic compounds. In *Citrus medica* L., Varga has identified three phenolic compounds which are present in eluates of inhibitor β, namely, salicylic acid, *o*-coumaric acid and either *p*-coumaric acid or ferulic acid. Ether extracts of *C. medica* L. made at Aberystwyth showed, in agreement with the results of Varga, that the inhibitor β is located at R_F 0·6–0·8 when chromatographed on paper with isopropanol/aqueous ammonia/water as solvent. After chromatography of the eluate with *n*-butanol/aqueous ammonia as solvent the inhibitor was located at R_F 0·4–0·6. This corresponds with the position of the inhibitor from *A. pseudoplatanus* in this solvent system. There were no reactions indicative of phenolic compounds in this region when chromatograms were sprayed with detecting reagents. Pure samples of the phenolic compounds mentioned by Varga were co-chromatographed on paper in *n*-butanol/aqueous ammonia with the eluate from R_F 0·6–0·8 of chromatograms of the ether extract from *C. medica* L. developed with isopropanol/aqueous ammonia/water. The R_F of the phenolic compounds did not correspond with the zone R_F 0·4–0·6 where inhibitor was detected by bioassay. Thus, the phenolic compounds mentioned by Varga are apparently not the major source of inhibition of extension-growth in coleoptile sections grown in the eluate of inhibitor β from *C. media* L.; the correspondence in the R_F values in two different solvent systems suggests that possibly the β-inhibitor in this species is related to the inhibitor of *A. pseudoplatanus*.

We thank Dr. J. W. Cornforth of 'Shell' Research, Ltd., for his helpful advice and collaboration on the chemical aspects of the work.

FUNCTIONAL COUPLING BETWEEN CELLS IN THE VISUAL CORTEX OF THE UNRESTRAINED CAT

By Dr. J. S. GRIFFITH and Dr. G. HORN
Departments of Theoretical Chemistry and Anatomy, University of Cambridge

THE discharge of cells in the visual cortex of two conscious, dark-adapted cats was recorded[1]. The depth at which the first unit showing a resting discharge was encountered by the microelectrode was taken as zero, and all recordings were made from units between this point and another lying not more than 3 mm deeper in the line of penetration. Spikes were amplified, monitored on an oscilloscope and recorded on magnetic tape. When an experiment was completed, the material stored on the tape was displayed on a cathode ray tube. Occasionally the electrode recorded the simultaneous discharge of two or three cells (cells 1, 2 and 3). When it was possible, on the basis of differences in polarity, amplitude and/or shape for the experimenter to discriminate reliably between the two or three sets of action potentials on the oscilloscope, the discharges were filmed. Records of 8 such pairs of cells were analysed together with one record which contained the action potentials of three cells. Each length of film was carefully examined manually, and each spike was classified as belonging to cell 1, 2 or 3 and marked accordingly.

The positions of spikes on the film were then measured in the following way. A length of film was laid across a screen over which would be drawn a cursor line moving from left to right over a distance of 10 in. Movement of the cursor line was measured automatically and the distances from zero at left automatically set up on a counter. The cursor line was placed over a spike and by pressing a button the reading on the counter was punched on five level paper tape. The cursor line was moved to the next spike and the procedure repeated. Spikes were identified on the punched paper tape by a symbol according to whether they were from cell 1, 2 or 3. The upper limit of accuracy of the measuring instrument was 0·001 in., and on no occasion was the interval between successive spikes less than this. When a 10-in. length of film had been measured in this way both film and cursor were drawn to the left, the counter set to zero and a symbol indicating overflow punched on the paper tape. The distances of spikes on the succeeding 10 in. of film were then measured from the new position. This procedure was repeated until the whole reel of film had been measured. The punched paper tape was printed out and compared in detail with the films to make sure the number and general distribution of spikes was correct and that the overflow symbols were correctly inserted. The paper tapes were then fed into a digital computer (*EDSAC II*) with a programme which gave further checks on the accuracy of the punching. Finally, the tapes were subjected on the computer to the analysis described here.

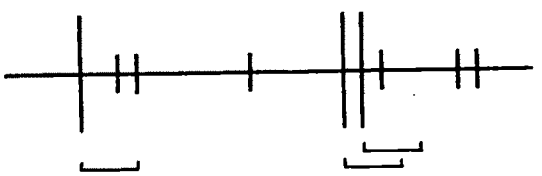

Fig. 1. Schematic diagram of a section of film containing spikes due to two cells. The square brackets show 5-msec intervals following cell 1 spikes

Statistical procedures. The object of the analysis was to see whether the firing of one of a pair of cells influenced the probability of discharge of the other. It seemed reasonable to suppose that this influence, if it were present, would last for a period of 10 or perhaps 100 msec. Accordingly we proceeded in the following way. Each time there was a spike due to cell 1 the number x_2 (0, 5) of spikes due to cell 2 in the next 5 msec was recorded. All these numbers were added together to give the total number X_2 (0, 5) of spikes of cell 2 which occurred within 5 msec after a spike of cell 1. In Fig. 1 three cell 1 spikes are shown together with their associated 5 msec intervals. The three corresponding values of x_2 (0, 5) are 2, 1 and 1 so that X_2 (0, 5) = 4. It will be noticed that the cell 2 spike which occurs in both the two overlapping intervals gives two contributions to X_2 (0, 5). Calculating the totals in this way is convenient because it then becomes easy to calculate the expected value of X_2 (0, 5).

BRITISH ASSOCIATION MEETING IN ABERDEEN

INVESTMENT IN MAN

By SIR ERIC ASHBY, F.R.S.
Master of Clare College, Cambridge

President of the British Association

1. Introduction

TWO hundred and seventy years ago James Blair, a graduate from Aberdeen and Edinburgh, secured a royal charter for the College of William and Mary in Virginia. Apart from Harvard, it was the only other place of higher education to be founded in North America in the seventeenth century. Blair became its first president. Its curriculum and statutes embodied the Scots tradition. This is but one example of the deep and lasting influence which Aberdeen and its University have had on the advancement of learning. Not only Virginia, but Pennsylvania, too, is in debt to Aberdeen for a heritage of higher education, for another Aberdeen graduate, William Smith, made an enduring contribution to the New World when he introduced in Philadelphia, as long ago as 1756, a curriculum comprising one-third classical studies, one-third science and technology, and one-third social sciences: a mixture which would nowadays be considered novel, but which was to be found in Marischal College two centuries ago. And here in Britain science and scholarship have been greatly enriched by men who have taught or studied in Aberdeen: physics by Clerk Maxwell, medicine by Patrick Manson, mathematics by George Chrystal, biology by Arthur Thomson and Chalmers Mitchell. There is no corner of the Commonwealth which has not been illuminated by the intellectual life of this City of Aberdeen.

This is the fourth occasion on which the City and University have acted as hosts to the British Association, and it is a great pleasure to begin—as my distinguished predecessors in Aberdeen began—by thanking the Lord Provost and the Vice-Chancellor, and all who have helped them, for inviting us here and for making such masterly arrangements for this meeting. For months people in this City have given up their energy and leisure to prepare for this week; at times they must have wondered whether these annual meetings are still necessary, and have asked themselves whether the aims of the British Association were not accomplished, and its mission completed, a generation ago. Anyone still assailed by such doubts as these should turn to the presidential address given here in 1885 by Lyon Playfair. Indeed, you would be well served on this occasion if I were simply to read Playfair's speech to you. Most of it is still as apposite as when it was written and it is composed with a wit and eloquence rarely equalled in presidential addresses to this Association. His mordant criticisms of the failure of Parliament to invest in science and education; his piercing comparisons between the financial support given to universities by governments in Britain and abroad; his advocacy of non-vocational teaching (illuminated by an epigram from Epictetus: "though sheep eat grass, it is wool which grows upon their backs"); his plea for research in universities; and his stirring conclusion ("the competition of the world has become a competition of intellect"): all these things still need to be said and have never been better said.

2. Investment in Man

But it is my duty to spin you something new, and I have a clear lead from last year's presidential address. Sir John Cockcroft spoke of "Investment in Science". The prerequisites for investment in science are, first, scientists, and second, a public opinion sufficiently well informed and enlightened to give financial support to scientists. Both these prerequisites are acquired through education. To invest in science you have first to invest in man.

Alfred Marshall once wrote that the most valuable of all capital is that invested in human beings. This is my theme. The advancement of science has its roots in the educational process. We have abundant evidence that our present investment in science is restricted by our educational policies over the past generation: you have only to study the pages of advertised vacancies for scientists and technologists to realize the extent of the restriction. Regarded in its lowest terms, investment in man brings high economic rewards; and in its highest terms, investment in man is a moral obligation which the State owes to its citizens. More than a century ago, in 1858, the Newcastle Commission on the State of Popular Education in England was told that "it is quite possible to teach a child soundly and thoroughly . . . all that is necessary for him to possess in the shape of intellectual attainment, by the time he is ten years old". We now invest more wisely than that in the young people of Britain but still not wisely enough.

Investment in man covers all kinds of education from primary school to the training of research workers. Even if we confine ourselves, as is proper on this occasion, to investment in man for the advancement of science, we are still left with too large a canvas. For you cannot isolate science. It is part of the seamless fabric of civilization. The advancement of science depends not only on the training of professional scientists; it depends also on the public image of science, and this is a product of the machinery which weaves science into contemporary culture; scientific journalism, science fiction, and communication of ideas about science through radio and film and television.

3. Resources of Ability

Having spread this scene before you I now ask you to follow me into one corner of it, to study it in more detail. Let us consider investment in man at the level of higher education alone. Within these arbitrary and narrow

limits, I shall discuss three questions: (1) What are the resources of ability for this sector of investment in man? (2) What policies and principles guide investment in these human resources? (3) What is the state of our knowledge about the social institutions we use as instruments for this sector of investment?

In 1962 some 113,000 boys and girls in Britain completed a course of secondary education with sufficient success to qualify them for some form of full-time higher education. They represent only about 14·5 per cent of the age-group, and of these only about half meet the requirements for entering a university. What has happened to the rest? Some 26,000 of them embarked on a grammar school course but left before taking the General Certificate of Education examination at the Ordinary Level or the Scottish Leaving Certificate, and some 474,000 of them left school before they reached the age of sixteen. Of course, the education of early leavers is not necessarily over. Through further education schemes, apprenticeship with day release, and the like, both government and industry continue to invest in many of them. But apart from a very few, who later on will break away from work to go to college, these young people will not receive any further full-time education.

Let us for a moment concentrate on the human resources which are available for full-time higher education. What principles guide our investment policy for these boys and girls?

The facts are these. Last autumn about 64,500 of them enrolled for the first time as full-time students in universities and various kinds of colleges (about 30,200 in universities, about 15,500 in colleges of technology, schools of art and commerce and similar places, and about 18,800 in teacher-training colleges). This is only about 55 per cent of those qualified for higher education, drawn from the already depleted human resources in this age-group in Britain. Let me put the figures into perspective in this way. Consider five children born in 1943: an American, a Canadian, an Australian, a Russian and a British child. There is about a one-in-three chance that the American is now receiving a full-time higher education. The equivalent chance for the Canadian is one-in-six, for the Australian, one in nine, for the Russian, one-in-twelve, and for the British child—but only if one includes all those taking sandwich courses—also one-in-twelve[1].

No one supposes that these ratios represent differences in resources of ability between these countries. What, then, do they represent? They represent differences in policy for investment in man. These comparative figures are often used to support indignant arguments about the inadequacy of provision for higher education in Britain. They are quite unreliable for this purpose. They omit students enrolled in part-time courses, which are an integral and valuable part of our system; they omit the population of pupils in sixth forms, who are doing work equivalent to first-year university work in Australia, Canada and the United States; and they omit any consideration of failure rates. Thus, some figures were published recently comparing university enrolments in a dozen European countries, together with Canada and the United States. When the data are calculated as enrolments per age group, Britain is eighth on the list out of twelve, and comes below such European countries as Belgium, France, Greece and Sweden. But when the data are calculated as the number of first degrees (per median age of taking a degree) Britain rises to fourth place on the list. There is a simple reason for this: it is that the 'efficiency' of a British university (in deference to dons I put the word in inverted commas) measured by the number of degrees awarded compared with the number of students who enrol in the hope of getting degrees, is about 85 per cent in Britain, whereas the 'efficiency' of most universities abroad is much lower: in Canada the corresponding percentage is 66, in the United States it is somewhere between 50 and 60, and in Australia it is less than 60 (ref. 2). This striking superiority in 'efficiency' of British universities introduces the next point in my argument, which concerns the policies and principles which guide our investment in human resources.

4. Policy for Investment

The American and British systems illustrate two fundamentally different approaches to investment in man. The Americans have an open door to higher education. Anyone who has completed a high-school course may claim admission to some university or other. The degree course is an obstacle race open to all competitors who care to enter it; the competitors can even choose whether to enter for difficult races with formidable obstacles, by going to universities of international standing, or to enter for easier races with less-formidable obstacles by going to universities of more modest prestige. There are prizes, in the form of degrees, for more than half the competitors; and the race is not always to the swift: the keen, persistent dogged tortoise, provided he surmounts the obstacles, finds himself a prize-winner. The policy of investment is to maximize the human resources put into the machinery for investment. Even so, not all American talent by any means is invested in higher education. It has been estimated that in the 1950's even at the highest level of intelligence—the top 0·1 per cent of ability-level—only two out of three Americans graduate from college[3].

In Britain we follow an entirely different policy over investment in man. By the age of twelve the door to full-time higher education is all but closed to 80 out of 100 children. The remaining 20 are selected for specialized privileged schooling which brings them to the gates of colleges and universities, but only about 8 out of the 20 get in. We rigidly select a small group of young people and sponsor this group through a heavily subsidized education of very high quality under very good conditions.

British policy for higher education is tenable only on certain assumptions. The first assumption is that the techniques for selection are efficient, reliable and satisfy social justice. The second assumption is that the numbers of young people selected each year for different kinds of full-time higher education are sufficient for the nation's needs. The third assumption is that we offer acceptable opportunities for part-time further education to those who are not selected. None of these assumptions is justified. Our methods of selection assume that our intellectual resources are limited by genetic factors, and that when we select candidates to go to grammar schools or to universities we are drawing from the population those with the innate ability to profit from these privileged kinds of education.

Of course, the intellectual resources in a population are ultimately limited by its genetic make-up. But we have abundant evidence that it is not genetics, but inequalities in our society and inadequacies in our educational system, which at present limit our investment in man; and this is true even in the most affluent nations. There is now convincing evidence that thousands of children fall out of our educational system each year due not to lack of ability, but to lack of motive, and incentive and opportunity[4]. A child who succeeds in climbing the ladder of education has responded to a challenge. If there is no challenge there can be no response; and our machinery for selection, unlike that in many countries, is in fact a machinery for distributing challenges. The trouble is that no refinement of our methods of selection will solve the problem which confronts us; for the problem we set ourselves is not to select from among those who leave school the candidates who are likely to profit from higher education, it is to select from among those likely to profit from higher education the candidates lucky enough to be offered it: which is quite a different thing.

In these circumstances it is no adequate test of our methods of selection to follow the success or failure of

those we select; we must also follow the success or failure of those we reject. On the one or two occasions when this has been done we find what indeed we might have expected: that the majority of those rejected by one university got into another, or took degrees externally, and (in such statistical studies as have been made) the chance of academic success among the rejected candidates was no worse than that among the accepted candidates[5]. There is, as one might expect, a general correlation between success at school-leaving examinations and success in degree examinations. This is useful information for statistical purposes, for example, for calculations of the potential size of the university population in Britain; but, of course, it gives no reliable guide to the decision the admissions officer has to make: shall I admit John Brown or Peter Smith? It is ironical that the one feature of the investment of man in higher education which we have studied scientifically leads merely to the conclusion that we could invest a much larger proportion of the age-group than we do.

Three facts confirm this view. In 1952, about 20,000 freshmen entered British universities to read for first degrees; 80·6 per cent of them were successful. Five years later, in 1957, the number of freshmen entering British universities increased by about a third, to 27,000. Some people even then talked of a dilution of quality among students, about 'scraping the bottom of the barrel' but the proportion of this generation of freshmen who successfully graduated did not fall: it rose to 82·8 per cent. The second fact is that the combined percentage of 'good honours degrees' (first and upper seconds) rose from 18·6 per cent in 1952 to 21·4 per cent in 1958, although numbers of students graduating over that period also rose by 6 per cent. The third fact is that over the past five years (1957–62) the number of new Department of Scientific and Industrial Research studentships awarded (for research-training in science and technology) rose by 85 per cent, from 649 to 1,194; but the percentage of 'good honours degrees' among these new award holders remained exactly the same: 81·7 per cent.

We are uneasy in our search for talent. We spend a great deal of time and energy over the problems of selection and we are tempted to believe that there must be a 'right' way to select students for admission to universities, if only we could discover it. Of course there is no right way and it is vain to seek one. It is our policy for investment in man which leads us into this Calvinism of the intellect. "Every selection", said the German philosopher Jaspers, "is in some way an injustice. We delude ourselves when we think that we can avoid such injustice through rational and determined effort".

So much for the first assumption underlying our policy for investment in man. The second assumption, that our system of higher education is on a big enough scale to meet our future needs for scientists and technologists, is untenable in the light of recent studies of manpower requirements[6]. The third assumption, that there are acceptable alternatives for those who are not selected for full-time higher education, does need comment. There is nothing inherently unsound—indeed there are great merits—in systems of part-time further education integrated with employment. The trouble about these systems in Britain is their inefficiency. We can well be satisfied with a system of university education which, through the use of external examiners, secures a common standard for all first degrees in all British universities, and an 85 per cent chance that a student will reach this common standard. The worm which gnaws at our satisfaction is that we have worked out a successful solution to this problem of quality control at the expense of a far greater problem which we have shirked: the problem of how to invest efficiently in the rest of our resources of talent.

While our wastage rate in universities is commendably low, we cannot forget the heavy casualties among young people who do not get full-time higher education and who try to qualify themselves through night classes, day release and correspondence courses. If you question this, study the examination statistics for Ordinary National Certificates (where the failure rate is said to be 50 per cent: in one London technical college 42 per cent of the evening students working for National Certificate dropped out in their first year), and the examination statistics for bodies which award professional qualifications in accountancy, surveying, insurance, and the like; even the professional qualifications offered by the Royal Colleges of Physicians and Surgeons. Wastage rates such as these are not the fault of the colleges for further education. They do their best to teach well. They are the fault of our social system which denies to the part-time student an opportunity to learn well.

When I say that our national policy for higher education is based on untenable assumptions I do not advocate, as some reformers do, a huge proliferation of universities in Britain. An indiscriminate inflation of the volume of investment in man would certainly not pay off. We need to know far more than we do about the pattern of higher education which is likely to be relevant to the lives graduates are going to live. If there were more university places in Britain, there is no doubt that more students would go to universities and that they would get degrees. The problem is whether—given our present curricula and teaching methods and pattern of degrees—this would be in the best interests either of the nation or of the students themselves. We cannot dissociate any increase in volume of investment in man from change in the pattern of investment[7].

This brings me to the central theme of this address: the university as a social instrument for investment in man. There are of course other social instruments which contribute to the same end. By singling out universities I do not imply that other instruments are less important; it is just that we penetrate more deeply if we focus on a small part of the field.

5. Ecology of Universities

The ecology of universities is remarkable: they reach back to the Middle Ages and they girdle the Earth. From the plains of Lombardy they have been transplanted to the grey climates of northern Europe, to the African bush, to American cities. They have invaded the ancient civilizations of Egypt and India and driven out institutions deeply rooted in the indigenous culture. They have adapted themselves to totalitarian and to democratic societies, to rural communities and to urban technologies. But through time and space they have preserved something resembling a genetic identity: they remain unique as instruments for investment in man. I cannot define this identity but I can describe it from its products. At their best, universities endow the men and women who pass through them with a characteristic intellectual equipment: it is the capacity to reconcile orthodoxy and dissent. Let me explain: the intellectual life demands a respect for what has gone before and acceptance of a rigorous discipline to a tradition of learning. To this extent universities are a point of stability in society: they anchor a society to its own past. But orthodoxy is celibate; it breeds no fresh ideas; unless tradition is continually re-examined, it becomes oppressive. So, in the course of their evolution, universities have learnt not only to pass on a corpus of knowledge and ideas, but also to train students to disclose errors in knowledge and to question ideas. Some words Michael Polanyi recently wrote about science can be applied to all the activities of a university:

> "The professional standard of science must impose a framework of discipline and at the same time encourage rebellion against it . . . This dual function . . . is but the logical outcome of the belief that scientific truth is an aspect of reality and that the orthodoxy of science is taught as a guide that should

enable the novice eventually to make his own contacts with this reality . . . The capacity to renew itself by evoking and assimilating opposition to itself appears to be logically inherent in the sources of the authority wielded by scientific orthodoxy"[8].

To train young people in this dialectic between orthodoxy and dissent is the unique contribution which universities make to society. Any change in the pattern of universities which endangers this function endangers the society which the university serves. It is for this reason that universities have to combine teaching with research. It is for this reason that they must endeavour to include among their students those who have the combination of temperament and intellect to profit from this particular approach to learning. But universities could not stay in business if they concentrated on nothing but this unique function; indeed this function arises as a by-product of a bread-and-butter job of training men and women for the professions. It is for their bread-and-butter service that the public is willing to invest money in them, and it is on their discharge of this service that their efficiency is judged.

6. Lack of Research on Education

The very word 'efficiency' applied to universities is anathema to some academic men. But of course there is no reason why our instruments for investment in man should be immune from the criteria of efficiency any more than our instruments for government or for the administration of justice are immune. Nor is there any reason why we should regard research into the production of educated people as any less important that research into the production of steel or artificial fibres. But we shy away from the idea of education as a technology. The techniques of education in Britain have scarcely been touched by the scientific revolution. This is particularly true in universities: although dedicated to the pursuit of knowledge, they are reluctant to pursue knowledge about themselves. Despite the fact that the annual expenditure on universities in Britain exceeds £70 millions, expenditure on studying the processes of teaching and learning at university level is negligible. Indeed, this distaste for research extends over the whole field of education. Despite recent grants by the Ministry of Education and the work being done by the National Foundation for Educational Research, and the imaginative projects being supported by the Nuffield Foundation, the fact remains that the proportion of expenditure on research in education to the annual expenditure on education in Britain is less than one-twentieth of a penny in the pound. Any industry which devoted so little to research and development would collapse.

Accordingly, when we come to ask whether our universities are appropriate instruments for investment in man, we lack the data to provide an answer. Each question we ask leads us into untested assumptions. To test whether the assumptions are valid we need to undertake a sustained programme of research on British higher education. Until this research is done the questions remain unanswered.

7. Utilization of Teachers and Buildings

The prime question concerns the future of the academic profession. Britain is already committed to a large expansion of higher education. There is already widespread criticism that the scale of expansion is far too small. For the next twenty years we know where the students are coming from and we have good reason to believe that there will be jobs awaiting them, in Britain or overseas, when they graduate. We know how to put up buildings to accommodate the increased numbers. What we do not know is where the teachers are coming from. Even on our present over-modest calculations for the universities alone (and they account for only about half the traffic in higher education) it is estimated that some 8,000 more teachers will be required, over and above replacements. Prophecy is dangerous, and I may well be proved wrong; but in some subjects—especially in mathematics, science, and technology—there is good reason to anticipate either a decline in quality of university teachers or a shortage in quantity[9].

It would seem prudent under these conditions to do some operational research on teaching and learning in universities. A convenient starting point is a phrase frequently heard nowadays: 'the burden of teaching'. You hear this more commonly than you hear doctors refer to the burden of healing or lawyers to the burden of litigation. The burden of teaching is measured by a mystic number called the staff–student ratio. This has its origin in the Talmud. Two millennia ago the Rabbi Raba established the rule "25 students are to be enrolled in one class. If there are from 25 to 40 an assistant must be obtained. Above 40, two teachers are to be engaged". One might have thought that with the advent of printing, the film, closed-circuit television, and the tape recorder, this ratio would have diminished. But in British universities it has increased to about one teacher to ten students—a higher ratio than is to be found to any other European country or in the United States. It is taboo in the academic profession to contemplate any diminution in this ratio. It must be emphasized that the cause of the higher ratio is the smallness of the denominator rather than largeness of the numerator: it is another consequence of the British policy for investment in man. So, as we change this policy by admitting larger numbers to higher education, we face a dilemma, in any event in mathematics, science and technology: Is it better to retain at all costs the quality of university teachers, even if it means less teaching per student and an increase in the staff–student ratio ? Or is it better at all costs to maintain the present staff–student ratio, even if it means the recruitment of some mediocre teachers, so that (as one American university president put it): "the teacher can communicate his mediocrity in an intimate environment" ?

The rational way to pursue this question is to anatomize the working day of a university teacher. According to estimates made by the University Grants Committee, nearly half his working time is spent in research. Let us concede straight away that this time must not be eroded; for although a lot of research is trivial and is (I suspect) done for reasons other than an enthusiasm for the advancement of knowledge, yet this is the seed-bed for creative work and it must be left undisturbed. The balance of his time spent in administration and teaching. Good management can always minimize administration. The difficult question is whether the techniques of learning and teaching in universities could be improved. There is evidence that they could. For some years the Fund for the Advancement of Education in the United States has promoted a massive and sustained programme of operational research on teaching and learning in American universities[10]. The results of this research, together with such fragments of work as have been published in Britain[11], are sufficient to dispel any complacency we may have about the efficacy of our teaching methods, and they make nonsense of any doctrinaire assertions about staff–student ratios.

Research on learning and teaching is notoriously difficult to interpret, for students are astonishingly resilient and adaptable creatures. Give them less teaching, and they compensate by working harder on their own. Introduce some novelty, such as teaching by closed-circuit television, and they may respond favourably not because it is a better method of teaching but because it is a novelty. However, when allowance is made for all these sources of error, the results of research indicate beyond doubt certain simple conclusions about university teaching. The first is that, for formal lectures, large classes are better than small ones, if only for the simple reason that the lecturer takes more trouble to prepare them. As

everyone who has to give lectures knows perfectly well, if he has to address 500 people, and especially if his address is to be televised or filmed, he is, as it were, raised to a temperature of excitement which makes for a better performance.

Secondly, as one would expect, the experiments confirm the value of teaching by discussion in small groups. But what size of groups ? The amount of teaching to be done is increased four-fold if tutorials are taken in groups of three instead of in groups of twelve. Is there any evidence that teaching is always more effective if the groups are very small ? There is not. Indeed, such little evidence as we have indicates that for some subjects a seminar of twelve is more effective than a tutorial of three. Thirdly, there is convincing evidence that students do better in examinations if they are left to work on their own and are not over-taught. This is a truism; three centuries ago Comenius wrote that his object was "to seek and find a method by which the teachers teach less and learners learn more". The novelty is that the methods known to Comenius can now be improved. If students working on their own have access to audio-visual aids they can cover, at their own choice of time and at their own pace of working, the more didactic parts of a course with very little formal teaching.

Fourthly, there is a growing body of evidence—enough now to justify very serious attention—that modern techniques of instruction such as language laboratories, films, taped discussions and (for certain parts of certain subjects) programmed instruction, are useful for some teaching even at university level. These technical devices save the teacher time which he can use more effectively in the intimate encounter of discussion which no modern technique can replace. Far from dehumanizing and mechanizing instruction (a charge frequently brought against them) these modern devices allow the individual to work on his own, at his own pace: they actually encourage individuality. Programmed instruction, for example, which some people ridicule as an instrument for university teaching, is merely a return to the Socratic method (even though the content is not Socratic): the student cannot remain passive; he takes part in a dialogue which makes continuous demands on the learner and evokes a continuous response from the teacher[12].

The introduction of technology into teaching and learning at university level evokes such emotional reactions that it is difficult to persuade some people to contemplate it objectively. Of course, gadgets cannot replace the teacher when he is really engaged in education and not just instruction, for in teaching at the highest level there has to be a feed-back from students to teacher, to which the teaching is constantly adjusting itself. But a good deal even of university teaching is at a lower level than this, and the aim of technology should be to relieve university teachers of this more didactic instruction. Professors once had to reconcile themselves to the invention of printing, which enabled the solitary student, alone in his room with a book, to confront the great teacher through the printed word. It is known that some of them protested, just as, centuries earlier, teachers had protested against writing as a substitute for oral tradition. Now, after nearly 500 years without much change in the technology of higher education, professors will undoubtedly have to reconcile themselves to new inventions, which will enable the student to confront the great teacher in a new and vivid way. Of course, we witness only the rudimentary stages of this transition. We are at that awkward phase when the techniques follow the old vestigial patterns, just as the first written instruction still retained the form of dialogue and the first printing resembled manuscript written with a quill pen. Under the impact of research into the techniques of teaching and learning the whole pattern of education is likely to change. Just as the good teacher of to-day is complementary to the book and the laboratory, so the good teacher of to-morrow will be complementary to the lecture by television, to the voice recorded on tape, and to the scientifically planned programmes for didactic instruction.

The technology of teaching and learning is only one point at which there is need to examine our equipment for investment in man. Another point is the efficiency with which we use the capital spent on universities. It has been estimated that the capital which a university invests, on buildings and equipment alone, for a science student is £2,400, and for a student in technology is £3,500. The bulk of this expenditure is on laboratories.

What assumptions are made in designing these laboratories ? First, that the undergraduate population in the university will not be using them for more than about 26 weeks in the year; secondly, that the programme of practical classes will be so arranged that all, or most, of the students in a course will be doing practical work at the same time; an elementary laboratory, therefore, may be empty for all but two or three afternoons a week in term time. Could the capital which is locked up in this way in the scientific laboratories of British universities be put to better use ? And should we continue to build scientific laboratories to the pattern traditional in British universities ? We simply do not know. What we do know is that research into the utilization of laboratories would be worth doing, for it has been done elsewhere and the results are instructive. A recent analysis in the United States showed that among eighteen different institutions of higher education there was a difference of 400 per cent between the lowest and highest use made of classrooms and laboratories and that in some institutions a rearrangement of the time-table to spread use evenly through the week could have led to very great savings in the capital investment per student educated[13]. A report, published in January 1963 [14], describes how forty institutions of higher education in the United States, ranging from liberal arts colleges to universities with enrolments of more than 15,000, have rearranged their academic years to increase the use they make of their buildings and equipment. Their main purpose in doing this has been to increase the rate of flow of students through higher education.

8. Curriculum

We have so far been discussing the efficiency of the university as an instrument for investment in human resources, and we have dealt with matters which lend themselves to simple statistical and experimental techniques. But to consider only problems susceptible of measurement would be to shirk the really difficult questions about universities, which concern matters which cannot be measured. The assumptions we make about the teleology of a university—its function—are just as much in need of scrutiny as the assumptions we make about its operation. It is at this point we confront the most difficult question of all when we consider universities as instruments for investment in man: What do we want our system of higher education to do for the people we put through it ?

The chief assumption we make about this question is evident from the pattern of courses in English civic universities. In most of them the great majority of students in arts and science are reading for special or honours degrees. This pattern presupposes one of two assumptions: either that these students are going to become professional scientists and scholars, or it presupposes that the training appropriate for an academic is the best training to give students who are not going to become professional scientists and scholars. The second assumption may well be correct, but at present we hold it only as an article of faith; and so it will remain until we know more about the sociology of professional life. The first assumption is easily disproved. In 1959 and 1960, for example, no fewer than 8,441 students graduated in one or other of the single honours subjects: history,

classics, English and modern languages. Of these only 739—about 8 per cent—are reported as having gone on to research and advanced study. Was this intensive training, largely in a single arts subject, the best way to invest in the other 92 per cent of these graduates? In science and technology a larger proportion—about 20 per cent—are reported as having gone on to research and advanced study, and many of the others went into posts where they were required to do scientific work. But again one asks whether the intensive training, especially the long period spent in the laboratory learning practical techniques, was the best way to invest in the 80 per cent or so of graduates in science and technology who did not go on to high-level academic research. It is a system we copied from Germany in the 1860's. Whether it is still the best way to invest the time of a British student in the 1960's we do not know.

We make untested assumptions not only about the pattern of courses, but also about their content. Here is one example. All but the most deeply entrenched pedants agree that education should be relevant to society. It is for that reason that medieval students read theology and renaissance students read Greek. If we begin to catalogue the characteristics of our own age, we soon find that among the outstanding features of modern life is what Peter Drucker has called "application of systematic knowledge to work". This activity is now part even of our cultural atmosphere, invisible because of its very familiarity. People engaged in mass communication, from the advertising agent who writes a toothpaste advertisement or who boosts a new car model, to the scientist broadcasting on the causes of lung cancer or the technology of rockets, assume that their words will be more convincing if supported by scientific evidence, graphs, statistics, data. This—much more than household gadgets and transistor radios—is technology diffusing into the common culture. But education has not yet accepted technology as a form of humanism. The idea that there is no point in learning history unless you are going to become a historian would be treated (and rightly so) with contempt. But the idea that there is no point in learning technology unless you are going to become a technologist still seems perfectly natural. In fact this idea is just as deserving of contempt, for already no man can regard himself as adequately educated who does not understand something of the principles of technology: by which I mean the art and science of the application of systematic knowledge to work.

9. Obsolescence

Finally, there is one more assumption built into our present policy for investment in man which is of critical importance. Education (as Charles Carter said recently) "is not an act of salvation, after which one is safe for eternity". Yet we assume it is: in particular, that a three-year undergraduate course is sufficient to set a man up for a lifetime. Doubtless in the nineteenth century a three-year course in classics did set a man up for a lifetime; but that was in the days when a graduate could assume that he would grow old in a world familiar to him as a youth. We are living in the first era for which this assumption is false, and we have not yet faced the consequences of this fact. The present generation of students will still be employed in the year 2000; but long before then their degrees and diplomas—in any event in science, technology, and the social sciences—will have become obsolete. The only students who can be sure of escaping obsolescence are those very few who will themselves become innovators. Our investment in the rest—the great majority of our human resources—will inevitably be devalued by technological and social change. Measures to combat obsolescence, therefore, become of prime importance.

What measures have already been taken? There is a plentiful supply of scientific and professional journals. But this is not enough: re-education, like education, requires challenge and response, an encounter between teacher and student. Refresher courses offer this, but the extent to which they are used, and the scope and duration of most of them, are pitifully inadequate to meet the need. Let me give you some examples. The Ministry of Education, and many other bodies, arrange short courses for teachers, covering such topics as mathematics, science and audio-visual aids for the teaching of modern languages. These courses are very valuable, but most of them last only for 4–7 days. There are some one-year full-time courses of advanced study, but during 1961–62 they were attended by fewer than 400 teachers[15]. There is no evidence that any educational institution is planning to offer sustained courses of re-education on a scale massive enough to prevent widespread obsolescence among teachers.

In technology the story is similar. Some universities and colleges put on short courses of re-education for technologists, but by no stretch of imagination could these courses be regarded as a comprehensive system to prevent obsolescence[16]. In the training of physicists and chemists there is no sign that any provision is to be made. For medicine the University of London has set up the British Postgraduate Medical Federation, which last year offered courses for general practitioners attended by more than 2,000 doctors; but most of these courses were only for week-ends or single weeks; and again they cannot meet the need for sustained and systematic re-education to prevent obsolescence in the medical profession[17].

So this is how we stand. We already spent large sums, even if they are inadequate, on higher education in Britain. It is probable that we shall be asked to spend a great deal more, in a massive programme for investment in man. A large proportion of this expenditure will be devoted to science and technology. But this investment in man will inevitably depreciate as the volume of effort in science and technology increases throughout the world. There is need for drastic steps to prevent obsolescence. Here is an opportunity for the extra-mural departments of our universities (which are, in any event, seeking for a new inspiration).

Of course universities and colleges cannot alone sponsor a programme to combat obsolescence. There will have to be co-operation from all forms of employers, releasing men on full pay for sustained full-time courses every few years. Perhaps the time may come when a degree or a professional qualification, like a passport, is valid only for a limited number of years, and is renewed only after attendance at a systematic course of re-education. The task of higher education is (in the words of the President of the Carnegie Corporation) to provide a "framework within which continuous innovation, renewal and rebirth can occur". In the disturbing, storm-swept, feverish thirty-seven years remaining to this century, nothing less than this will suffice for investment in man.

I thank Dr. Alvin C. Eurich and Dr. A. H. Halsey who read this address in draft and made many valuable comments on it.

[7] Sheer increase in amount of education is not necessarily worthwhile. Thus, Fritz Machlup (*The Production and Distribution of Knowledge in the United States*,, Princeton, 1962) demonstrates how, by increasing the efficiency of American schooling, the amount a child learns between the ages of 6 and 18 could be learnt between the ages of 5 and 15, and that an accelerated programme which brought the school-leaving age down from 18 to 15 might save the United States 10,000 million dollars a year.

[8] Polanyi, M., "The Republic of Science", *Minerva*, 1, 59 (1962).

[9] This assertion is open to challenge but it is supported by several pieces of evidence, for example: (*a*) in 1960, when an increase in student-numbers to 170,000 was contemplated, the President of the London Mathematical Association at the time calculated that 286 new entrants to the academic profession in mathematics would be required, and that the estimated number available was 14 a year; it might therefore take 20 years to accomplish this recruitment. (*b*) It used to be assumed that by and large a recruit to the academic profession should have a first-class honours degree. About 7 per cent of honours graduates are awarded first-class honours. This is at present an annual output of a little more than 1,000. The need for recruits into the academic profession, excluding replacements, is of the order of 8,000 if student numbers are to rise to 150,0000.

[10] This work is summarized in two publications by the Fund for the Advancement of Education, namely, *Decade of Experiment*, 1951–61 (1961) and *Better Utilisation of College Resources* (1959). See also *Ann. Conf. Higher Educ.* (University of Michigan Official Publ. 61, No. 80, 1959).

[16] Sir Peter Venables has been kind enough to give me a breakdown of the refresher courses offered by 67 colleges, including colleges of advanced technology and regional colleges. It is as follows:

Duration	*Courses*
2–7 days	169
2–3 weeks	34
4–6 weeks	18
8–10 weeks	8
3 months	2
6 months	1
9 months	3

Under existing regulations of the Ministry of Education a teacher may be seconded to industry full time for 6 months on full salary, but very little advantage has been taken of this, probably owing to the severe shortage of teachers.

SUMMARIES OF ADDRESSES OF PRESIDENTS OF SECTIONS

HIGH-VOLTAGE INSULATION

DR. J. S. FORREST chooses for the subject of his presidential address to Section A (Mathematics and Physics) "High-voltage Insulation".

Insulating materials for high voltages may take the form of a gas, a solid, or a liquid, or a combination of these.

The gas commonly used is air at atmospheric pressure, and by spacing the conductors far enough apart, as in power transmission lines, very high voltages can be insulated. In a uniform electric field the breakdown strength of air is 30 kV/cm, but in practice, especially at large spacings between conductors, the field is usually far from uniform and the breakdown voltage gradient is reduced, for example, to 6 kV/cm for gaps of several metres. For very long gaps, as in lightning, the average gradient is only 1–3 kV/cm. It is interesting to note that the whole range of breakdown voltage of air, from short sparks in the laboratory to lightning flashes of several kilometres in length can be broadly represented by a simple power law:

$$V = 0{\cdot}7\, d^{0{\cdot}85}$$

where V is the peak breakdown voltage in megavolts and d the sparking distance in metres.

If the gas pressure is increased the breakdown voltage increases, reaching a value of 300 kV/cm for nitrogen at a pressure of 315 lb./in.^{2}. With certain electronegative gases, still higher values can be attained; for example, 800 kV/cm for sulphur hexafluoride at a pressure of 215 lb./in.^{2}.

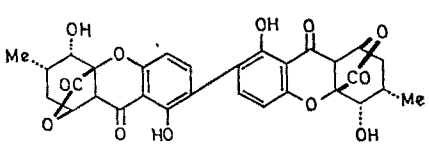
Solid insulating materials will withstand even higher voltages, and, under carefully controlled laboratory conditions, figures of about 8,000 kV/cm have been recorded for the puncture strength of mica. Breakdown in solids may, however, occur at very much lower gradients due to relatively slow processes such as thermal instability and discharge erosion. The breakdown strength of solids is very much less over the surface than through the solid itself, and the surface failure of insulation is much the most frequent cause of trouble in practice. If the surface of the solid is contaminated by moisture and conducting deposits, the breakdown strength is drastically reduced. With porcelain or glass insulation such surface deposits give rise to a very irregular voltage distribution over the insulator, and breakdown, due to surface discharges, may occur at average gradients of only 0·2 kV/cm. With organic insulation, these surface discharges may decompose the material and cause permanent damage. Sometimes the damage takes the form of a conducting path of carbon progressively laid down by the discharges—a phenomenon known as 'tracking'. With other materials carbon is not deposited, but erosion of the material occurs and ultimately causes complete breakdown. These phenomena frequently cause failure in practice at average voltage gradients of less than 1 kV/cm.

Hydrocarbon oils are the commonest insulating liquids; they are used either alone or as an impregnant for solid insulation. Transformer oil has a breakdown strength of about 300 kV/cm, but oil-impregnated paper for high-voltage cable insulation has a breakdown strength of 1,000 kV/cm and represents the highest standard achieved in practical insulation technology. The chlorinated diphenyls also have good insulation properties and, as these liquids are non-inflammable, they are used where there is a serious fire risk.

The practical working stress on high-voltage insulators of all types is only a very small fraction of the electric strength of the insulating material itself under good conditions. Some margin is necessary, but attempts should continue to be made to reduce the gap. Progress can be made by achieving more uniform voltage distribution on large insulators, and by inhibiting cumulative and progressive processes which lead to breakdown.

A PHYSICAL APPROACH TO CHEMICAL STRUCTURE

IN his presidential address to Section B (Chemistry), Prof. J. Monteath Robertson reminds us that the past fifteen years have witnessed extraordinary advances in the power of the physical methods that may be used to investigate chemical problems. During that time the



method of nuclear magnetic resonance has been developed and the scope of the other methods of absorption spectroscopy enormously increased by better instrumentation. The old science of X-ray crystal analysis has been transformed by the invention of the electronic digital computer. In other directions equally dramatic advances have been made, as in mass spectrometry, electron microscopy, the use and application of isotopes, the development of the various powerful methods of chromatography, and so on.

The determination of molecular structure is by no means the sole or even perhaps the most important aim of chemical investigation, but it is an important part. The purely chemical method based on degradative investigations can now be powerfully supplemented by an imposing array of physical tools. Many of these new methods resemble the chemical one in that they can be used to inspect certain portions of the molecular structure, identify certain groups, and gradually help to build up a complete picture of the molecule.

The method of X-ray analysis is entirely different. It cannot be used to look at a particular part of the molecule, or diagnose the existence of specific groups. It can only look at the complete structural unit and every atom it contains in a single operation. The waves scattered by the different atoms combine together by the principles of optical interference, and only the resultant can be observed. But if the structure can be solved, the answer obtained is far more complete than that given by any other method. It provides the exact position of every atom in space and so solves the chemical structure and stereochemistry completely in every detail.

There are two main obstacles in X-ray analysis. The first is the fundamental problem of determining the relative phase relationships of the scattered rays. This can usually be overcome by the 'heavy atom' or 'isomorphous substitution' methods[1], where use is made of an added extra atom which alters the resultant amplitude in a way that depends on the unknown phase. The second obstacle is the very formidable amount of computation involved in solving a complex structure. But this problem is now largely overcome by the invention of the electronic computer.

A good recent example of the power of the X-ray method is the determination of the structure and stereochemistry of ergoflavin[2], which can now be written as:

This is one of the colouring matters of ergot, the product of a fungus which grows on rye, and which has long been known to contain a complex group of medically important substances. Prof. W. B. Whalley was able to prepare a suitable heavy atom derivative of ergoflavin which he sent to Prof. Robertson for X-ray analysis at the end of November, 1962. The structure was solved completely by the middle of March this year, less than four months after receiving the crystals.

Work of this kind is greatly increasing our detailed knowledge of the structure of various natural products. A great effort is now being made to utilize these powerful methods to obtain information about the many vastly more complex biological molecules that are so vitally important in living matter. Substantial progress has recently been made, and solutions for some of the simpler protein and enzyme molecules are now in sight.

SOME ASPECTS OF DIAGENESIS

THE period between deposition and metamorphism of a sediment, for long the most obscure stage in its history, forms the theme of Prof. J. H. Taylor's presidential address to Section C (Geology). Recognition of its importance to oil geologists in determining the capacity of a rock to hold and transmit fluids and to mining geologists in giving rise to oxidate and reduzate ore deposits has done much to stimulate interest in the sequence of events that takes place.

Recognition of the fact that diagenetic processes represent attempts to attain equilibrium under changing conditions has given rise to the concept of diagenetic grade. Rocks which have been subjected to similar post-depositional history may be said to be of the same diagenetic facies. Mapping of the deposits of the Verkhoyansk geosyncline in Siberia has revealed a series of zones of regional diagenesis passing finally into albite-epidote-rich rocks of the greenschist facies.

Diagenetic changes can conveniently be considered in three main stages: (1) those taking place immediately after deposition, before burial beneath the next layer of sediment; (2) those occurring during early burial and leading to lithification; (3) those operating at considerable depth but not directly due to crustal movement.

Changes prior to burial may result either from transfer of material from the fresh waters of a river to a more saline environment or from changing conditions within the basin of deposition—changes controlled in large part by biological activity. On the sea-bottom *p*H commonly ranges from 7·8 down to 7·0 (somewhat less in restricted environments) and *Eh* from 0·3 to −0·3. Among reactions which take place, perhaps the most widespread are the cation substitutions which modify clay minerals and the transformation of a variety of layered silicates to glauconite.

During early burial *p*H and *Eh* remain major controls of diagenesis. Evidence from sea-bottom cores shows that a downward decrease in *Eh* may be accompanied by either a rise or fall in *p*H. Clay minerals undergo structural modification, carbonate and siliceous concretions develop, primary cementation includes the formation of overgrowths on detrital grains and the partial infilling of pore spaces with a variety of materials of which silica and carbonate are most widespread. Unstable forms of calcite, such as high magnesian calcite and to a less extent aragonite, give place to the more stable form. In sedimentary ironstones some replacement of earlier constituents by chamosite and much replacement by siderite occurs. Pyritization is widespread.

After deep burial, temperature and load pressure replace *p*H and *Eh* as the significant controls. Some indication of the diagenetic environment and of the chemical reactions that have taken place can be gained from a study of deep formation waters, the brines which must presumably largely represent concentrated connate waters. Data regarding these brines are unfortunately distinguished by quantity rather than quality. They indicate a decrease in the ratio of magnesium, sodium, potassium and sulphate to chlorine as compared with normal seawater and an increase in calcium, lithium, strontium, barium and boron. Sodium and potassium have presumably been used in the development of secondary micas, feldspars and zeolites; magnesium has replaced calcium in dolomitization and has also gone into the formation of chlorites and micas. Sulphate has been reduced to sulphide. Complicated sequences involving solution, redeposition and recrystallization of cements can be recognized under the microscope. Interpenetration of grains as a result of pressure cementation is widespread in sandstones, but less common in carbonate rocks. A variety of diagenetic sulphides has been recorded in small amounts in sediments. How far they can be developed in economic

quantities is problematical. In certain deposits they appear to be replacements of diagenetic pyrite but not themselves indisputably diagenetic.

It is pertinent to ask how the great volumes of hot connate brines expressed upwards from compacting sediments differ from the hydrothermal solutions of classical ore genesis. The limited available data regarding composition of mineralizing solutions, from fluid inclusions in ore and gangue minerals and from a recent borehole for geothermal power in southern California, show some remarkable resemblances to deep connate waters. Increased concentrations, relative to chlorine, of potassium and boron, however, suggest additions from some other source.

THE UNITY OF ECOLOGY

DR. F. FRASER DARLING discusses the "Unity of Ecology" in his presidential address to Section D (Zoology).

Both words, 'ecology' and 'economics', stem from the same root, to do with home: both deal with income and expenditure, economics with anthropocentrically considered wealth symbolized as money, ecology in terms of energy and conversion cycles. In communities of plants and animals, ecology is also an observational study of communities which covers the more general definition of ecology as the science of organisms in relation to their environment, and the interrelations of organisms inter- and intra-specifically. Psycho-ecological factors are now being identified and social behaviour can be of critical significance ecologically. Hunting and food-gathering man may be considered a member of the indigenous fauna; agricultural, pastoral, industrial, natural-resource exporting man is like an introduced species, the outstanding difference between him and the rest of creation being his political nature, which is of great ecological significance. The present wave of nationalism in a contracting world could have damaging results on the resource base and the future state of survival of the human species. Man was able to civilize, that is, take advantage of his innate capacity for communicative gregariousness, by learning how to tap the organically derived climax wealth of the planet, thereby giving himself leisure for social and artistic evolution. Originally, the concept of community in ecology was considered in its competitive characteristics; but the fuller present-day thought of plants and animals, including man, being the ecological community embraces co-operative qualities as well, so that the community is greater than the sum of its parts.

There should be no plant, animal and human ecology as separate entities. There is but one ecology, with man being considered actively and historically. History, so commonly recorded politically, might be re-written ecologically, with benefit for the future. The rise and fall of the English wool trade from Saxon times to the end of the medieval period is given as an example. A wider study in space and deeper in time is made of the development of nomadism in the Old World and the place of the horse as a riding animal in triggering the eastward Indo-European migrations and later the westward Mongol movement. Archæological evidences supplement ecological observations and inference.

Comparison is made of old-world nomadism of domesticated animals moved slowly over wild lands at man's wish, with the North American nomadism with the wild bison which developed when the Indians gained the horse from the Spaniard. The tempo of movement was set by the bison and there was consequently no overgrazing or impoverishment of terrain. This nomadism of wild animals on wild lands could have continued indefinitely as a biological continuum, but it specialized the Plains Indian and made him more vulnerable in a changing world from which his resource base was removed. Some reflexion is made on the projected cropping of wild animals on the wild lands of Africa. Ecological management is now possible, but historical consideration and comparison are inadequate. Ecology is always concerned with process, and conservation, which is ecology in action, the social application of ecology, must reach deeper into the studies of history, anthropology and archæology.

BRITISH NATIONAL PARKS

THE national parks of Britain form the subject of Prof. H. C. Darby's presidential address to Section E (Geography). The ten national parks of England and Wales have been created under the National Parks Act of 1949, and they cover about 9 per cent of the country. Much of their character can be explained by two general considerations. In the first place, there is the small size of England and Wales, the limited amount of relatively wild land, and the absence of public domain land from which parks could be created and owned by a national authority as in the United States and elsewhere; the territory within a British national park remains in private ownership. In the second place there is the existence not only of a highly developed system of local government but of very extensive planning legislation, consolidated and extended by the Town and Country Planning Act of 1947. The National Parks Act of 1949 in no way replaced the existing machinery of planning. Planning control within the parks, as elsewhere, remained in the hands of local authorities. It is true that a National Parks Commission was established; but this is essentially an advisory body, and its role is to see that the interests of amenity and access are not lost amid the clamour of many competing claims.

It must be said that the machinery created by the Act of 1949 has the merit of ingenuity. It has made the most of a limited area of land, and it has taken advantage of an established system of planning. It has skilfully used the principle of multiple land use, and it has sought to combine local and national interests in the management of the parks themselves. Yet when all is said, the fact remains that something is not well. Successive debates in both Houses of Parliament have directed attention to weaknesses in National Park arrangements. Wherein does the failure lie ? In the Act itself ? In the operation of the Act since 1949 ? Or in both ?

The Act certainly contained within itself the seeds of difficulty. It charged the Commission it created with two divergent tasks: (*a*) the preservation and enhancement of natural beauty in England and Wales; (*b*) the encouragement of facilities for open-air enjoyment in National Parks. The challenge thus presented to the planner was that of reconciling the different purposes of amenity and access. If this was the challenge presented in 1949, How much greater is it to-day? Only too often a crowd transforms what it has come to enjoy and destroys what it most admires. Rising standards of living, holidays with pay, and about three times the number of motor-cars on the road, have greatly increased the pressure on the remaining areas of open country and especially on the coast. Furthermore, the whole *tempo* of national life has changed, and may yet change to a far greater degree. Some of the main intrusions into the countryside come from Government Departments themselves and from the great statutory undertakings and large private developers—from oil refineries, for example, from water authorities, from the Service Ministries and from the Central Electricity Generating Board. It is inevitable that many proposals for development within a park should come into conflict with the aim of maintaining the scenic beauty and rural solitude of this or that area.

Some of the frustration and despondency about national parks may well spring from the attempt to deal with as much as nearly one-tenth of the country. Clearly, not only the standard of control, but also the degree of financial aid, may need to be different in different parts of our parks as at present delimited. There may well be a case for closely examining all the parks, and for establishing within each some kind of classification from a scenic point of view. The varying needs of open-air recreation also need to be assessed. At present British national parks lack the basic information necessary for sound planning decisions. But the planning officers of nine of the ten parks are also responsible for the remainder of their respective counties, and the staff of the Commission (including administrative, technical and clerical officers) numbers only 30. The simple fact is that there is not enough manpower on the job. How can three field officers cope with the variety of questions that arise ? Very little money has been spent on the parks—taking the country as a whole, less than a penny a person a year. The future of the parks could be transformed with the aid of a relatively modest increase in expenditure, in manpower and in technical expertise. Finally, in the light of 14 years experience and of the changing circumstances of the country, the Act of 1949 now stands in need of amendment.

FUTURE OF THE AEROPLANE IN THE CIVIL AND MILITARY FIELDS

IN his presidential address to Section G (Engineering), Dr. S. G. Hooker describes the "Future of the Aeroplane in the Civil and Military Fields". The cost of developing aircraft and engines is now so high that Government financial support is essential.

In the military field the industry is maintaining the full strength of the Royal Air Force and developing important new aircraft such as the *TSR* 2, *P* 1154 and novel types of transport.

In the civil field it is engaged on the *VC* 10, *BAC* 111 and the Anglo-French supersonic airliner *Concord*.

The exports of the industry are worth between £100 and £150 millions annually, and it is to be hoped that the *Concord* will gain a large share of the market which will arise when the 500 big jets at present in service become obsolete.

If we can produce a transatlantic airliner with a cruising speed of Mach 2·2 the current journey time to New York will be approximately halved, occupying about 3 h. A further increase in cruising speed to Mach 3 would save only about 0·5 h because of the increasing proportion of time spent in take-off, climb, descent and landing. Present knowledge of supersonic flight stems from military aircraft, which have been attaining supersonic speed since about 1950. Mach 2·2 was chosen for the *Concord* because higher speeds would prohibit the use of an aluminium structure or of conventional rubbers and plastics.

The overall thermodynamic efficiency of a turbojet is increased at supersonic speeds and should reach 50 per cent at Mach 2·2.

The engine chosen for the *Concord* is the Bristol Siddeley *Olympus* 593, a development of the engine used in the *Vulcan V*-bomber and *TSR* 2 supersonic strike aircraft. Such an engine will produce horse-power of the order of 100,000 at Mach 2·2 at 36,000 ft., which indicates the order of difficulty of its development.

Great efforts are being made to ensure that the *Concord* is at least no noisier than present jets. The high rate of climb will help to attenuate the noise heard on the ground near airports and if the transition to supersonic speed occurs at something over 40,000 ft. the sonic boom should not be an appreciable nuisance. Sonic boom, however, may limit the size and range of future supersonic airliners.

The *Concord* carries more fuel and less pay-load than a subsonic airliner, but has greater productivity because of its high speed. Compared with a *Boeing* 707, the potential revenue per hour of the supersonic transport is 50 per cent greater, while its operating costs are greater by only 20 per cent.

There is an urgent demand for vertical take-off, single-seater strike aircraft capable of high subsonic speed at ground-level and supersonic speed at altitude. Such an aircraft could well be of the established single-engine type provided that the engine can both lift and propel it. The Bristol Siddeley *Pegasus* has been designed for this purpose and has been flying successfully in the *P* 1127 *VTOL* strike aircraft.

The *Pegasus* has a large front fan which supercharges the high-pressure compressor and supplies by-pass air which is expelled through two nozzles on either side of the engine near the front. The exhaust from the turbines emerges through a similar pair of nozzles at the rear. All four nozzles can be directed downward or in any angular position up to the horizontal to give lift, thrust or a combination of the two.

Such an engine has the following advantages: (1) conventional installation; (2) choice of conventional, short or vertical take-off; (3) freedom from erosion and re-ingestion problems; (4) simplest possible installation and maintenance.

The *P* 1127 was never intended for supersonic speeds and the more advanced Hawker Siddeley *P* 1154, capable of both supersonic speed and vertical take-off, is now being developed.

In the lift/thrust engine for the *P* 1154 the thrust at the front nozzles can be doubled by burning additional fuel in them. The extra power is available for vertical take-off as well as supersonic flight. This type of engine has obvious application to both civil and military transports.

The ramjet is a simple engine depending on high forward speed for efficient operation. At speeds above Mach 3 it is becoming the most efficient powerplant known to man.

Flight at hypersonic speeds—above about Mach 5—is possible provided that suitable combinations of speed and altitude are observed. At such speeds the ramjet is the only possible air-breathing engine.

Studies show the possibility of an aircraft weighing 300,000 lb. and carrying a payload of 20,000 lb. over a range of 4,000 miles at 4,000 m.p.h. at altitudes between 100,000 ft. and 200,000 ft. and may be the reality of to-morrow.

THE TENTACLES OF TRADITION

IN his presidential address to Section H (Anthropology) Mr. Peter Opie considers folklore and "The Tentacles of Tradition". In the nineteenth century men of culture awoke to the possibilities of a new source of knowledge, and urged each other to garner the "fast perishing relics of the common people". Since then the investigation of folklore has grown in significance as it has become evident that the relics are not fast perishing, do not belong only to the common people, and are not necessarily relics.

It is becoming clear that folklore, while retaining ancient characteristics, is a living force which readily adapts to changes in environment. While some customs wither away and their memory becomes romantic to us, others prosper to such an extent that they become ordinary, even tawdry, and possibly commercialized.

In A.D. 960 it was ordered "That every Priest industriously advance Christianity, and extinguish Heathenism, and forbid the Worship of Fountains". To-day it scarcely matters which spring, well, pool, or fountain we visit,

we find the nation to be obsessed by the idea that it should lighten its pocket whenever it sees contained water. At Bridlington more than £35 was found, placed for no valid reason, in the pool of the Illuminated Gardens. At Kingswear in Devonshire the Parish Council collects almost £100 a year from a local wishing well. In Hull, when an ornamental fountain was erected at the corner of Jameson Street and King Edward Street in May, 1956, £67 was found in the fountain before the end of June, and in 1959 it was reported that coins were being thrown in at the rate of £8 a week. To-day churches and charities foster the cult by making pools where no pools were before, to their own pecuniary advantage. It might be argued that people to-day do not throw coins into water out of superstitious belief. But why is it that they are more willing to throw their money into water than to place it in an offertory plate? Is not the answer that if they throw coins into a pool of water they feel they are getting something in return for their money—they are purchasing 'luck'?

One of the causes of malnutrition in Bantu homes is that women of child-bearing age are usually forbidden to drink milk, because it is believed to cause sterility in females. Are we ourselves less haunted by fear of sterility? Belief that sterility will follow certain courses of action has been found associated with the women's services, factory workers, parachutists, and air hostesses. Many of the secret 'facts' which pass by word of mouth behind closed doors about, for instance, conception, contraception, menstruation, and sex-determination turn out to be traditional, and sometimes to have antecedents that go back to the time of Pliny. The fall of man occurs, day after day, when he gives way to his desire to believe in the mysterious and the far-fetched.

In 1962, in a debate in the House of Lords on pest poisons, a peer asked why vermin needed to be poisoned, when his mother-in-law had cleared her chicken-run of rats simply by asking them to leave. Far from being new, this method of disinfestation was practised in Scotland a century ago. It was well known to the Elizabethans, including Shakespeare and Ben Jonson, and was described in classical antiquity. But whereas the writer eighteen hundred years ago had been sceptical, the Under-Secretary of State replying to the debate in the House of Lords had declared that he firmly believed that there was "something in these extraordinary powers" which some people possessed.

It is possible that the extent of man's supernatural and superstitious credulities remains constant, and that the beliefs merely take on more sophisticated forms. There does not seem to have been any slackening in man's desire to believe the unbelievable. Individually we cradle ourselves in comfortable thoughts of sudden fortune, the inevitableness of destiny, the possibilities of re-incarnation, or the compensations of an after-life. The human mind has been equipped with a wonderful capacity for accepting evidence which agrees with its preconceptions. We are transfixed not so much by what we do not know, as by what we think we already know.

THE CONTRIBUTION OF CLINICAL MEDICINE TO PHYSIOLOGY

THE "Contribution of Clinical Medicine to Physiology" is described by Prof. J. McMichael in his presidential address to Section I (Physiology and Biochemistry).

Physicians and physiologists work increasingly together in the analysis of reactions to disease. Sometimes the physiologist points the way to new discoveries of value in medicine, but equally frequently the clinician's observations give an answer to problems before the physiologist is able fully to comprehend the situation. The value of orange and lemon juice in scurvy was recognized by Lind 180 years before vitamin C was isolated. Muddled thinking lost this discovery in the nineteenth century with many disastrous consequences, including the loss of Scott's polar expedition. Endocrine and brain disorders are best studied in man, and the co-operation of an intelligent patient with an observant doctor has repeatedly clarified physiological functions and pointed the way to further investigations.

Clinical observation can proceed a certain distance but completion of the analysis may depend on animal experiment. A good example was the observation of fibrillation of the heart by McWilliam in Aberdeen in 1888. The recognition of fibrillary contraction of the auricles in man was completed by James Mackenzie in 1906.

The use of man for planned physiological experiments was started by J. S. Haldane, who found that the regulation of respiration could be best studied in co-operative human beings. These techniques for respiratory investigations have now been enormously elaborated and constitute the basis of measurement of function of the heart and lungs in human disease. One of the commonest disorders affecting the heart is narrowing (stenosis) of the mitral valve. This obstructs the flow between the left auricle and the left ventricle. Because of this narrow passage the pressure rises in the blood vessels of the lungs. The use of a short-life isotope of oxygen enables measurements to be made of the blood-flow through different parts of the lungs. In mitral stenosis most of the obstruction to flow results from thickening of the arteries in the lower parts of the lungs where blood-flow is retarded. This contrasts with the state of affairs in normal subjects where, owing to the influence of gravity, there is a higher blood-flow in the lower parts of the lungs and a diminished blood-flow in the upper part. These findings give some explanation of why tuberculosis (now a disappearing disease) develops at the apices of the lungs where blood-flow is poor. This disease was known to be rare in mitral stenosis where the blood-flow at the upper part of the lungs is now known to be high. The reason why the arteries of the lungs become thickened and narrowed at the bases may throw light on the mode of development of thickening of the arteries elsewhere in the body. Disease of the arteries is perhaps the major cause of death and studies which began for the purpose of illuminating the lung circulation may in fact have a much wider significance in relation to arterial disease in man.

The clinical observer is exposed all the time to an enormous experience of a multitude of disorders which exercise his complete range of biological knowledge. He must compare continuously his experience and knowledge of disease with the reactions observed in physiological experiment. Modern medicine is becoming increasingly scientific in its methods of study and the mutual efforts of clinicians and physiologists will illuminate innumerable problems on which future individual human welfare depends.

CEREBRAL LOCALIZATION OF PSYCHOLOGICAL FUNCTION

THE idea of cerebral localization of psychological function is discussed by Prof. O. L. Zangwill, president of Section J (Psychology). This idea goes back at least to Gall, whose reputation has suffered unduly on account of his allegiance to phrenology. Although Gall must take his share of blame for the absurdities of phrenology, his ideas have had a good deal of influence on the development of modern neurology, especially through Hughlings Jackson, who derived much of his evolutionary doctrine from Herbert Spencer, in early life a disciple of Gall. It is also noteworthy that Bouillaud, the first to localize aphazia to the frontal lobes, was a strong admirer of Gall.

The development of physiological work on the brain from Flourens to the present day is outlined. It is pointed out that early work on the motor cortex gave rise to the

belief that this part of the brain is in some sense the 'organ' of voluntary movement. This inference cannot, however, be sustained. Nor can the cortical sensory projection areas be accepted as the 'seat' of sensory experience. We appreciate to-day that neither elementary sensations nor elementary movements are appropriate units for the analysis of behaviour and that we should concern ourselves rather with higher-order products of cerebral organization.

The attempt to investigate integrated behaviour patterns by physiological techniques is then considered. It is pointed out that as a number of primitive behaviour patterns concerned with the control of appetite, sleep and the simpler aspects of emotional expression appear to be organized at the diencephalic level, it would seem appropriate to speak of these behaviour patterns as having a measure of localization. Mention is made of the value of techniques of stimulation through implanted electrodes in the unrestrained, conscious animal in extending our knowledge of the functions of these deeper regions of the brain.

The effects of ablation of the brain cortex on the learning and retention of habits in mammals is then discussed. Following the work of Lashley, it is widely believed that habits have no very precise localization and are affected by the extent rather than the locus of a cerebral lesion. But it is important to bear in mind that Lashley himself did not reject the concept of localization. Further, more recent work, especially with primates, has given evidence of the differential localization of a considerable number of acquired behaviour patterns.

The problem of inter-hemispheric relations in learning and performance is briefly considered, with special reference to the work of Prof. R. S. Sperry. This leads on to some discussion of asymmetry of cerebral hemisphere function in man and the problem of cerebral dominance.

In conclusion, it is pointed out that cerebral localization is not so much a matter of delimiting 'centres', each with its own intrinsic 'function', as of specifying integrative foci in systems which may well comprise large areas of the brain and their inter-connexions. In spite of some recent assertions to the contrary, it is contended that examination of the defects resulting from injury to the brain, whether in animals or man, does in fact throw light on the cerebral bases of normal behaviour. It may even turn out that the ideas of Gall, for all their *naïveté*, will, in the long run, prove more relevant to our understanding of brain function than cybernetic models of the kind now in vogue.

THE TROPICAL BOTANIST

BOTANY is a vast subject, growing unwieldy. It stretches from the physical and chemical workings of plant-protoplasm through the grosser structure of cells and tissues to the vegetation which they make. It is concerned with the most important and one of the most abstruse problems of life, namely, photosynthesis. It involves the classification of one of the most complicated sets of entities, namely, the half-million or more living plants which make up the vegetation of sea and land. It comprises the problems of their distribution, their origin and evolutionary connexions, their economic and cultural value to man, and the interpretation of fossil remains. It began as a science about the middle of its range when Linnaeus introduced the system of biological names. It spread with the excitement of the microscope and the voyages of discovery. It spreads with the ultra-microscope, the techniques of modern physics and chemistry, the progress of genetics and ecology, and the accumulation of collections of the world flora, both past and present. It leans on the other sciences, borrows from them, contributes to them and, yet, lacks its own mastery. Its extremes are now so far apart that they cannot be satisfactorily housed, financed, or understood in the same department. The older aspects of classification, plant-structure, life-histories, distribution, ecology, and natural history are referred to, sometimes with contumely, as classical botany. Its younger aspect, which links the minute workings of the plant with physics and chemistry, is being woven into the new science of cell or molecular or microbiology. The study of vegetation takes classical botany into the country. The study of micro-structure builds the new laboratories in the city.

Mr. E. J. H. Corner, in his presidential address to Section K (Botany), is concerned with the future of classical botany. It has ramified, and prospers now in many small fields. It is full of specialists. It has lost most of its applications to the sciences of agriculture, horticulture, forestry, fisheries and medicine. It is impoverished and avoids its main issues. It lacks the integration of a spontaneous science. It seems ripe for overthrow by the rising molecular biology.

This would be disastrous. It would destroy that which should unify our understanding and appreciation of all plants. It would destroy it before it has found its proper footing. Classical botany has still to familiarize itself with the majority of living plants, and this majority, which it has neglected in the tropics, is now in danger of extermination. Classical botany is needed by the applied and lucrative sciences, and the alternative of leaving them to foster the fragments which they require would be as unsatisfactory a surrender.

In order to survive, classical botany must be re-organized. First, it must face and accept the challenge to its stereotyped thought given by A. H. Church in Oxford in 1919. For a generation this outstanding issue has been evaded, but "the beginnings of botany" are in the sea, whence it must be re-developed. Secondly, classical botany must concern itself with the plants, the processes and the results of plant-industries. There is more money in bananas than in buttercups, in mushrooms than in mosses, in seaweeds than in pond-scums, in timber than in taxonomy. Thirdly, it must re-cast its morphology, ecology and classification from the tropical point of view. The neglect of this exuberance has caused the stagnation of the study of the land-flora.

The progress of tropical botany cannot be relegated to the slow rise of pure biology in the tropics themselves at the hands of their own biologists. The tropical countries are being industrialized, their leading students are being made industry-minded, and their floras, which are the richest heritage of plant-life, are being wiped out. Tropical botany must be sponsored from the seats of classical botany in the temperate countries, particularly by the interchange of university personnel. Probably no other natural science needs to develop so much the counter-stream of students to the tropics.

The tragedy of universal deforestation, so often short-sighted and purely for exploitation, brings home to the botanical traveller the fact that his science has no control over its natural resources. Botanists have for too long been content with the crumbs dropped by others from the lavishness of Nature's table. The feast is coming to an end, and botanists must take their stand in the conservation of what remains. They must assert themselves in this administration of world-affairs. Their classical science has the ingredients of leadership for human benefit.

THE BENEFICENT FOREST

THE aim of Prof. H. M. Steven's presidential address to Section K* (Forestry) is to consider what benefits woodlands can bestow, both in general and with special reference to the Highlands of Scotland and similar upland areas in Britain.

The natural climax vegetation on the Earth is some kind of woodland wherever the climate, and in some instances the soil, permits. At one time the whole of Britain was covered with woodland except on the higher hills, the bogs and the marshes. To-day, only 7·1 per cent is woodland. This contrasts with about 25 per cent, which is the percentage of the land area of the world covered with some kind of woodland. If, therefore, the forest is beneficent, we are claiming very little of its benefits.

We are apt to forget that the most fundamental thing in the world is the ability of green plants to utilize part of the energy of the Sun to manufacture products useful, directly and indirectly, to man and all other creatures. Recent work has shown that trees compare favourably with other useful plants in the efficient utilization of solar energy. Soil fertility can be built up by the forest, because most of the nitrogen and minerals in the trees are to be found in the growing tissues, such as leaves and twigs, and also in bark, and not in the timber of the stem; these are not normally removed from the forest and when broken down by innumerable organisms become available again for the growth of the tree. Except on the poorest soils, the nutrients removed from the soil are replaced by the slow weathering of soil minerals and the deposition of nutrients in the rainfall. The forest can be a self-perpetuating natural resource; this is the aim of systematic forestry. The principal alternative use of our uplands is grazing, mainly by sheep. Ecologists and indeed agriculturists agree that this is merely an extractive form of land use in most instances. The animal products so produced are rich in nitrogen and minerals and these are removed from the land; there is no beneficial cycle of returning nutrients as in the forest.

The progressive deforestation of Britain in the past has led not only to declining fertility of the soil but also to an impoverishment of the natural flora and fauna. Even the modest afforestation programme that has been carried out has led to some increase in the rarer woodland birds and mammals. There is already a widespread interest in Britain's native flora and fauna and this is likely to increase in the future.

It is important to know whether forest cover affects surface and sub-surface run-off of water compared with, say, grassland, because water is also an important natural resource. Investigations on this subject are proceeding in many parts of the world, including more recently in Britain, and the Department of Scientific and Industrial Research in 1961 set up a Committee on Hydrological Research. This is a difficult subject, and much more research on it is needed. Even although it is found that there is a lower yield of water under forest, there is general recognition of the higher permeability and greater storage capacity of soils under forest which lead to reduced surface run-off, hence less erosion, a more prolonged yield of water during drought, and lower stream-flood peaks. There is no reason, therefore, why the conservation of water resources should restrict the expansion of the forest area, particularly when much of the potential land for afforestation is in regions of high rainfall.

It is not necessary to argue the role of forestry in helping to stem rural depopulation because this has been emphasized by one committee after another in recent years. The principal contribution of forests to employment is not in the growing of timber but in its processing and utilization, the ratio between these two parts being about one to five. We are now seeing the first fruits of this in the setting up of the Fort William pulp mill, and its consequential effects; this, however, need only be the beginning.

Although these aspects of the beneficence of forests are important, the final role to be mentioned, that of a source of timber and other products, is still more important. Few fully realize that these are among the world's most important primary products with an estimated annual yield of 1,350 million tons. Thus, in terms of timber production also, Britain is making little use of this potential natural resource with only 7 per cent of the land surface devoted to forestry, and an annual import bill of more than £450 million for timber and products derived from it.

The forest policy adopted after the Second World War was to plan for a fully productive forest estate in Britain of 5 million acres, equivalent to about 9 per cent of the land surface—still one of the lowest in Europe. It was estimated that this would require about 3 million acres of additional land for forestry, and the new afforestation would require to be undertaken mainly by the State for economic reasons. The Forestry Commission have, however, experienced continuous difficulties in getting the necessary land, due mainly to the heavy subsidization of agriculture. A revised plan, begun in 1958, fixed planting programmes on a five-year basis but on a falling scale. It is true that, in this nuclear age, it is not necessary to have strategic reserves of timber for a long war, but the Zuckerman Committee, an independent body which did not include any members with forestry interests, stressed the continuing necessity for a vigorous forestry programme in these words: "We may therefore conclude that (regardless of the part which, as we shall argue later, forestry might play in slowing down depopulation and abandonment of vast areas of Great Britain) there is probably a stronger economic reason now than there has been hitherto for investment in planting trees". The policy at present advocated to secure this end is the integration of pastoral agriculture and forestry. Provided this was on a sufficiently large scale, included an adequate proportion of large as well as smaller areas for forestry, and a due proportion of the better as well as the poorer land, it could ensure that Britain had a greater share of the beneficence of the forest. It still poses unsolved problems, and Prof. Stevens concludes by advocating that substantial areas be acquired by the State in a number of upland areas in Britain to investigate and demonstrate the best ways of substantially increasing the productive capacity of such lands by steadily developing and enriching them instead of impoverishing them. He is certain that if the known techniques of improving hill pastures were fully applied it would be possible to release much greater areas of land for an extension of the forest and thus a fuller reaping of its beneficence, while at the same time maintaining hill farming at a reasonable level to provide the foundation stocks for the lowland sheep industry, and also to provide for the use of cattle to develop and maintain the potentiality of the improved grazings.

PERSONAL VALUES IN EDUCATION

WE are reminded by Sir Charles Morris in his presidential address to Section L (Education) that education in the United Kingdom is more generally credited with outstanding success in exploiting the values of the institutional factor than those of the personal factor. Britain's most famous schools and colleges are very famous indeed; and the greatest work of her most celebrated individual teachers has always been seen against the background of particular institutions, to whose service they usually devoted their lives. But for all that, personal relationships have clearly played a fundamental part; and the insistence on the central importance of the development of character, and on the education of the whole man, has kept the individual teacher, making a full use of his personality, in the centre of the stage. But in more recent times in this as in other fields of human endeavour, the immense potentialities of well-designed mechanisms and of imaginative blue-printing have made a powerful impression both on

educational theorists and on public opinion. First, the imaginative administrator and, more recently, the teaching machine, have come very much to the fore. It may be time to ask, Where is Britain going in all this ? Is she being compulsively attracted towards a system of automation, exploiting to the full the possibilities of self-education based on machines and pre-planning ?

In these days, when there are large numbers of students and small numbers of teachers, there are considerable practical difficulties in ensuring that the sparks are able to pass to and fro in this lively relationship and it will undoubtedly be necessary to rely more and more on well-designed systems of instruction, and it will be necessary to invent even more ingenious machines. It will be necessary for teachers to make the fullest possible use of the machine tools of the technology of education, so as to make the human efforts of the individual man or woman more extensive in their impact and more intensively productive. But the key-stone of education lies in an interpersonal relationship. Britain has sometimes been in danger of forgetting this both in the grammar schools and in the universities. She has gone ahead as if good syllabuses and a well-arranged timetable can of themselves alone do the whole job. Certainly they cannot do so; if what is being looked for is true education, though they are quite necessary as conditions, they cannot carry Britain as much as half the way. There is no substitute for the real teacher; and the good teacher has to be able to establish a real relationship, pupil by pupil, with those whom it is his concern to educate. It is certainly going to be difficult enough in our time to ensure that Britain has a sufficient number of teachers. But the most difficult problem of all in the coming years is going to be to see that, in spite of the pressures of numbers, and in spite of the demands of specialism, the good teacher gets a chance to do his true job.

PROVIDING FOOD FOR MAN AND BEAST

BEFORE Section M (Agriculture), Prof. Martin Jones poses the question: Where has the human food come from in the past, and where will it need to come from in the future ?

The present increase in population needs a corresponding increase in the production of food, and the popular idea is that the limit of production will soon be reached as nearly all the land suitable for crop production is already in use.

Such a view ignores what the scientist can do to modify the methods of food production. The problem of food is how to collect the energy from light and convert that light energy into food energy either in the form of fruit and vegetables or as meat and milk. Only about a tenth of the light energy per acre is now utilized by our farm crops, even our most popular crops.

Improvements due to manuring and plant-breeding are playing their part, but the limiting factor over a vast area of the world's surface is the supply of moisture. Man needs only to harness the water and irrigate the large areas of desert in the tropics to bring about a ten-fold increase in the quantity of food available, particularly when combined with the use of modern manures. Experiments have shown that this method is practical and, furthermore, irrigation is spreading so fast that soon it will be regarded as a waste of manures if the requisite amount of water is not supplied with them, especially at the critical stage in the life of the crop.

This increase in the production of food in the tropical and semi-tropical deserts is already being done by enthusiasts who have the confidence to look ten years ahead and are prepared to spend the capital necessary for storing and utilizing the vast supplies of water available, even if it means conducting it through a pipe-line over a thousand miles.

Changes on such a vast scale may alter the distribution of the human race and encourage the people not only to grow their food in these drier areas but also to live there for choice of climate.

Such a development would no doubt guarantee the quantity of food for all; but we have now to guard very carefully that the food is of the right kind for the proper nutrition of the people, particularly young people. Here, with modern crops such as cereals which are easy to mechanize, there is a great danger of the diet lacking sufficient protein and the proper balance of the right kind of proteins, minerals and vitamins.

This balance could be helped very considerably through the use of more meat and milk—animal products based on grass, which requires not only suitable soils and manures but also modern methods of conservation and utilization.

This all adds up to limitless opportunities for an increase in our food production so as to keep pace with the increase in population for at least the next two hundred years, by which time even our proposed methods may again be out of date, if the human being should be able to get his supply of energy through some other means than a green plant. For the time being, however, the green plant is an essential link in collecting the energy of life for us, and it is our duty to study the needs and behaviour of such plants.

PROBLEMS OF PENOLOGY

A SCIENTIFIC penology, the subject of Prof. W. J. H. Sprott's presidential address to Section N (Sociology), is impossible to achieve until the principle of retribution is abandoned. Arguments are given against this principle. If the 'tariff' system of punishment is given up, penology becomes entirely forward-looking. It has three objectives: preventing the offender from offending again, either by deterring him or reforming him, deterring potential offenders, and the protection of the public. Taking the treatment of offenders alone, the first aim is to keep them out of prison, partly on economic grounds but mainly because of the deleterious effects of imprisonment.

To this end research is required into a typology of offenders and also a study of differential treatment. Reference is made to the work at present being carried out in California. Such treatment is particularly directed towards first offenders, but recent research has shown that many habitual criminals are in need of supervisory care on account of their social inadequacy. For them permanent hostels are recommended. The problem of general deterrence demands more research than has been devoted to it. The problem here is: Precisely at what classes of person is the deterrence of potential offenders directed ? Some classes of potential offenders are not likely to be deterred at all. Others may be, and here the question is: What threat will deter them? If deterrence of potential offenders is accepted as a justifiable aim, then some offenders will be sent to prison with this end in view, as will also be the case with those for whom non-custodial treatment has proved ineffective. The issue here is: What reformative influences can be brought to bear on them ?

Reference is made to three experiments now being tried out in Great Britain. The first is the psychiatric prison recently opened at Grendon Underwood, where prisoners referred by prison medical officers are treated and where the problem of treating the psychopath is being explored. The second is the attempt to bridge the gap between prisoner and custodial staff by means of 'group counselling'. The third is the open prison at Ashwell for recidivists where the régime consists of a minimum of supervision by the prison staff and maximum

responsibility given to the prisoners. The third aim of sentencing, the protection of the public, is a matter of weighing values and not a matter for scientific research. The question here is: What offences are considered so serious that society must be protected against them for long periods ? It is suggested that in the case of the persistent petty thief, society must be prepared to take risks. In the case of certain sex offenders and professional criminals society has the right to protect itself.

The final issues discussed are: the indeterminate sentence and the question of a sentencing tribunal. Arguments are brought against both of these. The indeterminate sentence is disturbing to prisoners who are not granted parole. If there is a sentencing tribunal then appeals against sentence will go before the courts and we are back where we started, and if sentencing is to have a general deterrent effect, then sentencing must be done as soon as possible after the trial. At the same time, it is suggested that special sentences such as corrective training and preventive detention should be abolished and the allocation of offenders sentenced to custodial care should be left to the prison authorities.

PRESIDENT FOR 1964 OF THE BRITISH ASSOCIATION

LORD BRAIN

THE RIGHT HON. LORD BRAIN, the well-known neurologist, has been elected president for 1964 of the British Association for the Advancement of Science. Lord Brain will deliver his presidential address at the next annual meeting (1964) in Southampton. The British Association has made what will prove to be an excellent choice, because not only is Lord Brain perhaps the first clinician to be awarded this important honour since Lord Lister, but also, like Lister, he is a medical man who has done much to set medicine on a scientific footing.

Lord Brain was born in 1895 and received his preliminary education at Mill Hill School and New College, Oxford.

At Oxford he was taught zoology by Sir Julian Huxley and for a time had J. B. S. Haldane as a tutor. He also came under the influence of Sherrington and Bazett. Proceeding to the London Hospital for his clinical work, he had as a teacher George Riddoch, fresh from his collaboration with Henry Head on the effects of war injuries on the spinal cord. Riddoch started him on his career in neurology by introducing him to Maida Vale Hospital, to the staff of which he was later appointed, and soon after that he became neurologist to the London Hospital.

There has always been a close link between neurology and ophthalmology, so Brain later joined the staff of the Royal London Ophthalmic Hospital (Moorfields), which led to his interest in the ocular symptoms of thyroid disorders, particularly exophthalmos, and his description of the syndrome exophthalmic ophthalmoplegia helped to clarify the endocrine factors responsible for exophthalmos.

Shortly after the War, his attention was directed to disorders of the joints of the neck as a cause of neurological symptoms, and this helped to open up a new field of clinical neurology dealing with spinal cord syndromes, and more recently with the effects of disease of the cervical intervertebral disks on the circulation through the brain. About this time, in collaboration with others, Lord Brain was one of the first to describe degenerative changes in the nervous system associated with cancer, and this has led to the recognition of a wide range of disorders complicating cancer, but not directly due to the spread of the growth, and he is now directing a team carrying out research in this field, with the support of the British Empire Cancer Campaign.

An early interest in psychology and psychiatry, stimulated by developments in psychological medicine during the First World War, led Brain to investigate the correlations between brain and mind illustrated by the effects of brain damage, and during the Second World War he wrote on some visual perceptual disorders and on the significance of handedness in relation to cerebral function, and recently he has performed work on disorders of language, thereby continuing the London Hospital neurological tradition springing from Hughlings Jackson and Henry Head. The physiology and pathology of perception and consciousness and their philosophical implications remain a continuing interest.

Lord Brain married Stella, daughter of the late Dr. Reginald Langdon-Down, whose father, Dr. John Langdon-Down, described mongolism, which has recently attracted much interest on account of the discovery of its basis in a chromosomal abnormality. Lady Brain has many medical relatives, and a cousin of hers is the wife of Prof. A. V. Hill, a former president of the British Association.

Lord Brain has many honours to his credit; a most intriguing point is that (1) his name is Brain (2) he is a world-authority on the brain; (3) he is the editor of the excellent specialist journal *Brain*.

THE ABERDEEN REGION

The North-East of Scotland

A Survey prepared for the Aberdeen Meeting of the British Association for the Advancement of Science, 1963. Pp. viii+256. (Aberdeen: The Central Press for the Local Committee, 1963.) n.p.

ALTHOUGH it is not usual to start reviewing a book from its end, in the case of this book, *The North-East of Scotland*, it seems the most obvious place. Between the last page and the cover is provided the best introduction to any area—a detailed map. The present one, a 1/5 in. to the mile coloured map, was specially prepared by Messrs. John Bartholomew and Son, Ltd., Edinburgh, for the occasion of the visit of the British Association for the Advancement of Science to Aberdeen—as was the *Survey* itself.

Twenty-four contributors, mainly from the University of Aberdeen, have produced a *Survey* full of information for the members of the Association. It consists of twenty-six essay reviews dealing with various aspects of the area, which for the most vary from two to twenty pages. It opens with a succinct account of North-East Scotland which, like a clenched knuckle, projects from the Grampians to the North Sea. Essentially it is concerned with the counties of Aberdeenshire, Banffshire and Kincardineshire, but in part Moray and Nairnshire are included.

Having thus defined the theatre for the British Association 1963 meeting, the platform is next laid out by essays on the geology and structure (13 pp.), geomorphology (17 pp.), climate (5 pp.), soils (8 pp.), flora (8 pp.), and fauna (13 pp.). North of the Highland Boundary Fault

are rocks of Precambrian age—the Highland Schists, metamorphosed arenaceous and calcareous sediments. Large sills of igneous rocks of Old Red Sandstone age have been intruded into these schists, and vary from granite to basic and ultra-basic igneous rocks. South of the Highland Boundary Fault, rocks of the Old Red Sandstone underlie the whole area. Between the Old Red Sandstone lowlands of Moray and Strathmore the knuckle projects into the North Sea as a complex of lowland and upland plateaux drained by numerous rivers, such as the Dee and the Don. Elements of highland and lowland scenery are interdigitated as straths and glens cut back into the hill masses producing a quilted effect, diversified by the contrast of glacial erosion. For example, the difference in the character of Deeside and Donside is the result of the abundance of fluvio-glacial material in the former:

> "The River Dee for fish and tree
> The River Don for horn and corn".

With increasing distance from the sea, the climate becomes more extreme and is heightened by the basin-like nature of the inland relief. As this pattern alters so also do the soil types, the flora and the fauna. Soils with free drainage occupy the flanks of the hills, imperfectly drained soils, the gentler contours on the lower slopes, poorly drained soils, the footslopes, and very poorly drained soils, the depression and the bottom lands. The flora of North-East Scotland is considered in the *Survey* according to four geographical elements, namely, the Continental Northern, the Northern Montane, the Arctic-subarctic and Arctic Alpine, each containing many interesting and rare species, for example, orchid, saxifrage, mountain avens, sedge, etc. On the other hand, the fauna is treated under six biological communities: mountains (including Arctic species, such as ptarmigan and mountain hare which turn white in winter), moorlands, forests, agricultural land, rivers and lochs, coast and sea. Each has its characteristic fauna, rarely purely natural, but usually a blend of naturally occurring and introduced species. The fauna includes rabbit, deer, wild-cat, stoat, salmon, pike, adder, golden eagle, grouse and seal, etc. The sections dealing with the flora and fauna are supplied with admirable lists of scientific and common names of species mentioned.

Essays follow dealing with the region before 1700, regional settlement and fishing villages 1750–1880. The first mentioned outlines the Mesolithic period with its associated pigmy flints, the area's Neolithic sequence with its important art of pottery making and chambered burial cairns. Then follow the incursive 'beaker folk' from Holland and later the Bronze Age and Iron Age settlements. The picture develops with the Roman penetration, and the Picts and Celtic Christianity. Later came the Viking raids, the feudal castles and the Normanization of Scotland and the attacks from Anglo-Norman England, culminating in the Civil Wars and the dethronement of Mary, Queen of Scots.

Each of the settlement types can be related to a phase in the historical development of the region; the crofts, the product of colonization during the agricultural revolution, representing the successors to the cottar's dwellings of the farming townships. Later come the mixture of agricultural and industrial influences. In the eighteenth century, fishing and farming are predominant in the economy, bringing more intricate contact with the diverse and open society of the mercantile centres.

Three eleven-page sections have been prepared on agriculture, forestry and fisheries. Farming and related industry and trade make up a large part of the economic life of the North of Scotland. Although there has been a movement of labour in the past century towards the townships, improvements have been achieved through automation and the many changes in crop and animal husbandry, which have raised yields per acre and per head of stock. The section on forestry deals with the historical background, State forests, private forests (10·6 per cent of the area), education, research and forest products. The area is one of the most important and most interesting regions for the forester in the whole of the British Isles. It is an area in which trees and woods have played a large part in the social history and where the art and profession of forestry are well understood. The University of Aberdeen is one of the four British universities which has a department of forestry and sets a high standard in its degrees in forestry. The review on fisheries indicates well the major changes which have occurred over the past century, and describes the more than 60 per cent of total Scottish fishing that is centred on the area: Aberdeen itself is the largest fishing port in Scotland and the third largest in the United Kingdom. The North-East collectively has become the chief centre in Scotland for the processing of fish by smoking, filleting and freezing, and for ancillary industries, such as shipbuilding, the manufacture of nets and of fish-meal, ice-factories, ship-repairs and supplies of all kinds. It is interesting to learn that the annual Scottish catch of salmon and sea-trout by angling and by commercial methods amounts to 1,500–2,000 tons—small compared with some species of marine fish, but in value representing an income to fishermen of £1·25–1·5 million.

By far the longest essay in the *Survey* (53 pp.) is that dealing with industries and commerce. The principal industries are fishing, distilling, granite, textiles, shipbuilding, engineering, food preservation and paper manufacture. A characteristic is the high degree of specialism which exists both in the processes of manufacture and in the finished products. Each of the industries is described geographically, historically and from the economic point of view of the annual turnover. For many centuries the manufacture of textiles has held a substantial place in the economy of Aberdeen and other towns, including linen, flax, canvas and, of course, woollen milling. The last-mentioned includes luxury cloth, scarves, plaids, tweeds, twist cheviot and worsted suitings. Whisky is one of Scotland's greatest exports and has had a long and eventful history. Most malt distilleries are to be found to the north of the Tay, and within this area the counties of Banff and Moray are by far the most important—the greatest concentration being in the Spey Valley region. Measured by employment figures, the distilling industry is relatively small, but in terms of value of output and value of exports it ranks very high. The paper industry is no exception, and a great variety of high-quality papers produced at the mills around Aberdeen are consigned to many overseas markets. The area, because of the large deposits of granite of high durability and beauty, holds an important place in the granite industry. As Aberdeen is the focal point of communication in North-East Scotland, the essay is rounded off with a pertinent account of these communication routes, giving details of inland transport facilities, trade, steamship lines, livestock forwardings, etc.

The essays which follow deal with population changes, local dialects, local government in Scotland, schools, the University of Aberdeen, research institutes (including details of the great three—the Rowett Research Institute, the Macaulay Institute for Soil Research and the Torry Research Station), technical education, Aberdeen College of Education, local scientific societies, the museums, the Highland Folk Museum at Kingussie, and scientists of the region.

Most of the essays are supplied with a list of selected references and a general index is provided which makes cross-referencing easy between the essays. All in all, the Local Committee of the Association is to be congratulated on providing a concise, readable account of the North-East of Scotland. Those members of the Association who were able to peruse it before the Meeting will have gained a useful insight of the North-East of Scotland; certainly it will help afterwards to gather together and supplement personal experiences.

(*Continued from page 876*)

In addition to finding the value x_2 (0, 5), the nineteen quantities x_2 (5, 10), x_2 (10, 15) . . . x_2 (95, 100) were recorded and again totalled to give X_2 (5, 10), X_2 (10, 15) . . . X_2 (95, 100). These totals refer to the number of times cell 2 spikes occur in successive 5-msec intervals after the firing of cell 1, up to 100 msec.

We were also interested in whether or not the firing of cell 2 influenced the subsequent firing of cell 1; so the same quantities were recorded with the roles of the two cells interchanged. These totals are X_1 (0, 5), X_1 (5, 10) . . . X_1 (95, 100).

We now assume the cells are firing independently of each other and calculate the expected values of the X_1 $(a, a + 5)$ and X_2 $(a, a + 5)$. Let there be n_1 and n_2 spikes of cell 1 and 2 respectively and the duration of the record be T seconds. Further, let m_1 and m_2 be the mean rate of firing per second of each of the two cells. Then n_1/T and n_2/T are the sample estimates of m_1 and m_2. The probabilities of a cell firing in a randomly selected short time δt are $m_1\delta t$ and $m_2\delta t$ for cell 1 and 2 respectively. For a longer period Δt, the expectations of the number of spikes are $m_1\Delta t$ and $m_2\Delta t$. Taking $\Delta t = 5$ msec, the estimate for the expected value of any x_2 $(a, a + 5)$ is $n_2/200T$ and for any x_1 $(a, a + 5)$ is $n_1/200T$.

Let us now consider, for clarity of exposition, a specific one of our totals, say, X_2 (0, 5), which has in fact been analysed in detail and is described here. This value is the total number of spikes in n_1 separate 5 msec intervals, in each of which the expected number of spikes is $m_2/200$. The numbers in the various intervals cannot be regarded as independent random variables because the distribution of the intervals depends on the statistical properties of the sequence of spikes of cell 1. However, the expectation of the sum is equal to the sum of the expectations even when the numbers are not independent (see ref. 2, p. 73) and hence the expectation of X_2 (0, 5) is $n_1m_2/200$. All the X_2 $(a, a + 5)$ have the same expectation for which the sample estimate is $n_1m_2/200 = n_1n_2/200T$. The corresponding quantities for X_1 $(a, a + 5)$ are $n_2m_1/200 = n_1n_2/200T$. The expected value is therefore the same for both X_1 and X_2.

Without a very detailed statistical analysis, which we hope to make later, it is not possible to give a completely rigorous test for whether an observed value for an X_1 or X_2 differs significantly from an expected one. However, it is essential to have some idea of what deviations may be regarded as significant and fortunately it is easy to derive an approximate test for a cell which fires fairly slowly relative to the interval considered and which occurs in a pair of cells, both of which do not have an entirely regular firing pattern.

We now write p_1 or p_2 for the probability that, respectively, cell 1 or cell 2 fires in a 5-msec interval. Clearly $p_1 \approx n_1/200T$ and $p_2 \approx n_2/200T$. We suppose p_1 and p_2 to be small so that $1-p_1 \approx 1$ and $1-p_2 \approx 1$, and we also assume that the probability of two or more firings of either cell in one interval may be neglected. Consider now X_2 (0, 5). Its distribution will be given approximately by a binomial distribution with parameters p_2 and n_1 (not strictly because the different x_2 (0, 5) are not entirely independent). This distribution in turn is approximated by a normal distribution with mean n_1p_2 and standard deviation $\sqrt{n_1p_2(1-p_2)}$ (see ref. 2, section 6.4). Using our sample estimate for p_2 we test the significance of the observed value of X_2 by assuming it to be a member of a normal distribution with mean $m = n_1n_2/200T$ and standard deviation $\sigma = \sqrt{m}$. Owing to the symmetry of the result, the same test applies to X_1. This test should be quite reliable for our results because, with one exception, all values of p_1 and p_2 are very small.

The other parameter of cell discharge which we considered was a function of the number of spikes from one cell of a pair counted in the 100-msec interval following the discharge of a spike in the other cell. This function was the mean, M_1, of all twenty X_1, that is, $M_1 = \Sigma X_1/20$ or the mean, M_2, of all twenty X_2, that is, $M_2 = \Sigma X_2/20$. Thus M_1 is the number of spikes from cell 1 present in the mean of 20 successive 5-msec intervals following a spike in cell 2 and vice versa for M_2. This 5-msec period will be referred to as the averaged 5-msec interval. In view of the analysis outlined in the preceding paragraphs it seems reasonable to compare the distribution of each of the two quantities M_1 and M_2 with a normal distribution having a mean $m = n_1n_2/200T$ and standard deviation $\sigma_1 = \sqrt{(m/20)}$.

To summarize, we have examined the question of whether the firing of one of a pair of cells (say, cell 1) influences the probability of discharge of the other (cell 2), by considering the number of spikes of cell 2 present in (i) the first 5-msec interval and (ii) the average of the twenty successive 5-msec intervals after the discharge of a spike from cell 1. We have analysed these results to see whether the values so observed deviated from the expected values which were estimated.

In order to assess the statistical significance of any deviation, a parameter was calculated which was a numerical statement of the magnitude of the deviation. In the case of the data from the first 5-msec interval, the parameter was $\lambda = (X-m)/\sigma$ and in the case of the averaged 5-msec interval $\Lambda = (M-m)/\sigma_1$. If the value of $|\lambda|$ or $|\Lambda|$ exceeded 3, it was considered that the deviation of observed from expected value was likely to occur by chance only rarely ($P < 0{\cdot}01$) and hence reasonable to conclude that the two values came from different populations.

Experimental results. Our experimental records comprise a total of 16,770 spikes corresponding to eight recording points with two cells and one recording point with three cells. In the case of three cells, the analysis was performed separately for each of the three possible pairs.

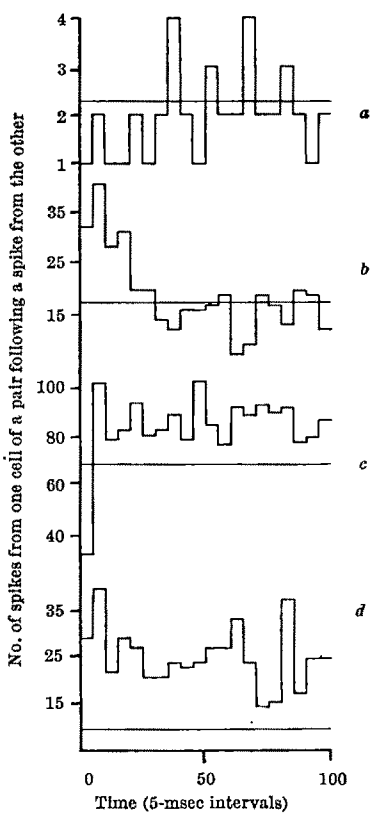

Fig. 2. Histograms showing, for selected pairs of cells, the number of spikes from one cell in successive 5-msec intervals after the firing of the other. The expected number is drawn as a horizontal line. The cells plotted are: (*a*) pair 8, cell 2 following 1; (*b*) pair 6, cell 1 following 2; (*c*) pair 2, cell 1 following 2; (*d*) pair 7, cell 2 following 1

Table 1. Properties of the Cells

n_1 is the total number of spikes due to cell 1 which were counted. m_1 is the mean rate of discharge of cell 1 in spikes/sec and p_1 the probability that cell 1 will fire in any randomly selected 5-msec interval. n_2, m_2 and p_2 are corresponding values for cell 2. T is the number of seconds over which the discharge of the corresponding pair of cells was observed

Cell pair	n_1	m_1	p_1	n_2	m_2	p_2	T	Cat
1	1,149	2·09	0·0104	46	0·084	$4·2 \times 10^{-4}$	551·0	35
2	355	2·31	0·0115	5,811	37·81	0·189	153·7	35
3	385	1·17	$5·87 \times 10^{-3}$	123	0·38	$1·87 \times 10^{-3}$	328·1	35
4	605	4·91	0·0246	168	1·36	$6·82 \times 10^{-3}$	123·2	36
5	641	11·50	0·0575	318	5·70	0·0285	55·8	36
6	554	3·92	0·0196	853	6·03	0·0302	141·4	36
7	1,792	3·79	0·0190	498	1·05	$5·27 \times 10^{-3}$	472·4	36
8*	2,707	6·35	0·0678	35	0·08	$8·7 \times 10^{-4}$	426·5	35
9 (12)	158	1·46	$7·31 \times 10^{-3}$	133	1·23	$6·16 \times 10^{-3}$	108·0	36
9 (23)	133	1·23	$6·16 \times 10^{-3}$	439	4·06	0·0203	108·0	36
9 (31)	439	4·06	0·0203	158	1·46	$7·31 \times 10^{-3}$	108·0	36

* Refers to 10·7-msec. intervals

Table 2. Correlation of Activities of Cells

X_1 and X_2 are the numbers of discharges of cells 1 and 2, respectively, in the first 5-msec interval following discharge of the other cell. M_1 and M_2 are the means for the first twenty 5 msec (except for cell pair 8, for which the interval was always 10·7 msec). λ and Λ measure the deviations from the expected values, significant deviations being underlined

Cell pair	Expected No.	X_1	λ_1	X_2	λ_2	M_1	Λ_1	M_2	Λ_2
1	0·48	0	−0·69	1	0·75	0·55	0·45	0·65	1·10
2	67·10	30	−4·53	50	−2·09	82·4	8·35	84·7	9·61
3	0·72	0	−0·85	3	2·68	2·3	8·31	2·6	9·88
4	4·13	3	−0·55	0	−2·03	4·7	1·27	0·4	−8·20
5	18·28	21	0·64	21	0·64	25·3	7·35	24·8	6·82
6	16·71	32	3·74	30	3·25	18·3	1·74	9·95	−7·40
7	9·45	23	4·41	28	6·04	28·4	27·58	24·3	21·62
8	2·27	2	−0·18	1	−0·85	3·15	2·60	2	−0·81
9 (12)	0·97	0	−0·99	0	−0·99	1·8	3·75	2·05	4·89
9 (23)	2·70	9	3·83	6	2·01	4·4	4·62	4·85	5·84
9 (31)	3·21	2	−0·68	0	−1·79	1·85	−3·40	2·5	−1·77

For one of the recording points with two cells the interval of time discussed in the last section was 10·7 msec, not 5 msec, owing to a different rate of recording on film. This is indicated in Table 1.

The mean rate of discharge (m_1 and m_2, Table 1) of the nineteen cells ranged from 0·082 to 37·8 spikes per sec with only one cell firing at a rate exceeding 11·5/sec. Accordingly, the probability that a cell would fire in any randomly selected 5 msec interval (p_1 and p_2, Table 1) was, with this one exception, low.

First 5-msec interval (Table 2). In four pairs of cells the number of spikes observed from one cell in the first 5 msec following a spike from the other, was significantly ($|\lambda| > 3$) different from the expected number. In cell pair 2, λ_1 was a negative quantity, which means that the discharge of cell 1 was reduced to below the expected level following a spike from cell 2. The value of λ_1, in pair 9 (23), was positive; so the number of cell 1 spikes following a cell 2 spike was significantly greater than the expected value. In cell pair 7, λ_1 and λ_2 were significant and positive. That is, the number of spikes of cell 1 following a discharge from cell 2, and the number of spikes of cell 2 following a spike from cell 1, were significantly greater than the expected value. A similar relationship existed between both cells of pair 6.

Averaged 5-msec interval (Table 2). In two cell pairs (1 and 8) the observed number of spikes did not differ from the expected number ($|\Lambda| < 3$). That is, the discharge of a spike from one cell did not influence the probability of discharge of a spike from the other. In three cell pairs (4, 6, 9 (31)) the deviation of the observed value from the expected value was significant for one of the cells of each pair. In each case, Λ had a negative value. This parameter was both positive and significant for the two cells in each of the remaining pairs.

The magnitude and sign of Λ for a given cell pair bore no obvious relation to the magnitude and sign of λ for that cell pair.

The way in which the values X (0, 5), X (5, 10) . . . X (95, 100) for one cell of a pair fluctuated about the expected value was not constant from one cell to the next. We have illustrated four fairly typical histograms of these fluctuations in Fig. 2. Each block of the histogram represents the mean number of spikes of one cell in a 5-msec interval following the discharge of a spike in the other cell. The twenty intervals from this event to 100-msec later are plotted. The horizontal line in each histogram represents the expected number of spikes. The histogram of Fig. 2*a* is that of cell 2 following cell 1 of pair 8. It may be seen that the observed number fluctuates irregularly about the expected value. In this case (Table 2) λ_2 and Λ_2 were both well below 3. Fig. 2*b* is the histogram for cell 1 following a spike in cell 2 in pair 6. After the first 20 msec, during which the number of cell spikes was increased well above the expected number, the histogram falls precipitously and fluctuates close to the expected level. In this case λ_1, > 3, but $|\Lambda_1| < 3$. The histogram of cell 1 following cell 2 of pair 2 is illustrated in Fig. 2*c*. For the first 5 msec the number of spikes is well below the expected level ($\lambda_1 = -4·53$), and thereafter remains above it, not returning to the expected level throughout the 100 msec analysed ($\Lambda_1 = +8·35$). Cell pair 7 also shows a rather curious pattern of behaviour. The data for cell 2 following a spike in cell 1 are plotted in Fig. 2*d*. Following the cell 1 spikes the number of spikes of cell 2 is increased for each of the twenty 5-msec periods, at no time returning to the expected value. We anticipate that if we had continued our analysis for a long enough period (for example, 10 sec) following the spike in cell 1 the observed number would fall to the expected number, for it must do so ultimately.

Discussion. With the exception of two cell pairs (1 and 8) the firing of one cell of a pair was influenced by the presence of a spike in the other. Sometimes (6 cell pairs) the influence operated both ways. These effects were demonstrated by at least one of the two analyses undertaken. The influence lasted a variable length of time. In some instances (Figs. 2*c* and *d*) a discharge from one cell altered the probability of discharge in the other for 100 msec. This effect was seen in a pair of cells which fired relatively slowly (pair 7, Fig. 2*d*) and in a pair (pair 2, Fig. 2*c*), one cell of which fired relatively rapidly (38

spikes/sec). The effect thus seems to be independent of the rate of discharge of the interacting units.

When the observed number of spikes differed significantly from the expected number in both cells of a pair the deviation was positive. When the observed number differed significantly from the expected number for only one cell of a pair, the deviation usually (4 out of 5 occasions) was negative. The physiological interpretation of these findings is almost entirely a matter of speculation. Where both cells influence each other they may do so by mutual facilitatory interaction. It is possible, however, that the discharge of the two cells is governed by a source common to both. If the activity of this source periodically waxed and waned, it could certainly produce the coupling effects which have been described. There is no suggestion whatever that the supposed source is common to all pairs of cells showing mutual interaction.

This hypothesis is less plausible for those pairs in which the firing of only one of the cells was influenced by the other. In such pairs it is possible that one cell tends (usually) to inhibit the other, though we might have expected the effect to have been reciprocal (see, for example, ref. 3).

Finally, it is of considerable interest that each of the two cell pairs (1 and 8) which showed no evidence of interaction contained a regularly firing cell[4] which discharged one spike every 12 sec approximately.

We thank the Radio Astronomy Group at the Cavendish Laboratory for their advice and assistance, the staff of the Mathematics Laboratory, especially Dr. David Wheeler, for their help and advice with programming, and the Medical Research Council for financial assistance.

A RAPID METHOD FOR EXAMINING STEAM-CORROSION AND STEAM-CORROSION INHIBITION

By LARS G. HOLMLUND
Royal School of Dentistry, Umeå, Sweden

CORROSION investigations have been carried out in the past both as practical tests and laboratory investigations. In the former so-called 'field tests', long corrosion periods were used and the attack was usually measured by registering the change in weight of the test sample and also by comparison with standard samples the corrosion of which had been graduated according to certain scales of measurement. The corrosion specimens varied in size and shape depending on the test involved. In field tests, it is desirable to use flat specimens with large surface areas. The laboratory investigations, on the other hand, were performed using small test samples of different shape. When the corrosion in these latter tests was not measured electrochemically, the test periods were often long, the length depending on the use to which the laboratory-type corrosion tests were to be put[1–3]. Other workers[4–6] have investigated a number of volatile amines in steam-heating systems and obtained evidence of considerable reductions in corrosion. Analogous investigations have, however, not been performed with regard to instrument sterilization in autoclaves.

The aim of the present investigation has been to investigate the corrosion of instruments during their sterilization in autoclaves and the possibilities of inhibiting this effect. For practical reasons, it has been necessary to carry out the investigations on small specimen rods. Moreover, during instrument sterilization, the corrosion times were relatively short. In order to examine more thoroughly the degree of corrosion and the effect of the corrosion inhibitor, model experiments were performed in glass apparatus in which the test samples were subjected to the influence of the same corrosion medium as in the autoclave (that is, steam and steam condensate) or to this medium together with a certain amount of inhibitor, that is, volatile amines. The temperature of the steam and steam condensate was 98°–99° C and the pressure atmospheric, and in this respect the experimental conditions differed from those in autoclave sterilization where both the pressure and temperature are higher.

De-ionized water or de-ionized water containing 0·1 per cent *cyclo*hexylamine was poured into a number of 'Pyrex' vessels equipped with ground-glass countercurrent coolers (Fig. 1). In each apparatus, a test sample was placed above the liquid surface on a 'Pyrex' glass support. The apparatus was then immersed in a constant-temperature water bath set at 99° C. Losses of liquid from the vessels were prevented by the counter-current coolers. Immersion lasted 120 min.

In this way the test sample was subjected to the influence of both steam and condensate. The specimen rods, which were cylindrical (length 45 mm and diameter 5 mm), were made from the basic materials used for different dental instruments. In this report, results are given for one type of material (SANDVIK 21*T*10*P*. Analysis (per cent): C = 1·25; Si = 0·15; Mn = 0·3; Cu = 0·25; W = 1·7; V = 0·1; Pb = 0·2) used in dental burrs.

The specimen rods, which had been stored by rubbing with oil, were selected at random, washed with ether and rinsed in de-ionized water as cleansing liquid. Then they were 'set to zero' by means of ultrasonic cleaning immediately before the start of the tests (Narda ultrasonic apparatus: Ser. 600).

Five test samples were cleaned at a time. Each sample was cleaned by itself in a separate 'Pyrex' test-tube using 5 ml. de-ionized water. The five test-tubes were fixed in special positions in a support in the ultrasonic apparatus. The ultrasonic cleaning has been carefully standardized (time, water temperature, depth below water surface,

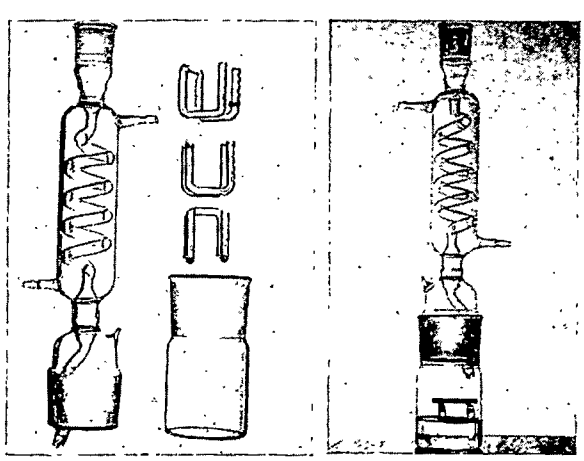

Fig. 1. 'Pyrex' corrosion apparatus. Individual parts on the left and assembled on the right

frequency, height of test-tube above bottom of ultrasonic tank, volume of liquid in tube, etc.) and each specimen rod has had, during the whole of the experiment, a definite position in the ultrasonic tank. Each cleaning period for each separate specimen lasted 2 min, and each sample was each time cleaned 10 times consecutively (cleaning period 1, 2, 3, etc.) in fresh test-tubes using de-ionized water (Fig. 2). Experiments have shown that the specimen rods, after this treatment, are satisfactorily free from oxidation impurities and from any damaged grains and grain boundaries (Fig. 2) resulting from the surface treatment. The different specimen rods were, in addition, more 'similar' to each other at the beginning of the corrosion experiment than they were before the ultrasonic cleaning (Fig. 2)[7]. After the corrosion test, the specimen rods were once again purified in an analogous manner.

The amount of 'corrosion products', expressed as the amount of dissolved iron/cm² surface area, was determined by analysing for the amount of iron in each cleaning solution from each separate cleaning period using a modified orthophenantroline method[7].

A comparison of a series of experiments on one type of test specimen shows that, if the steam contains *cyclo*-

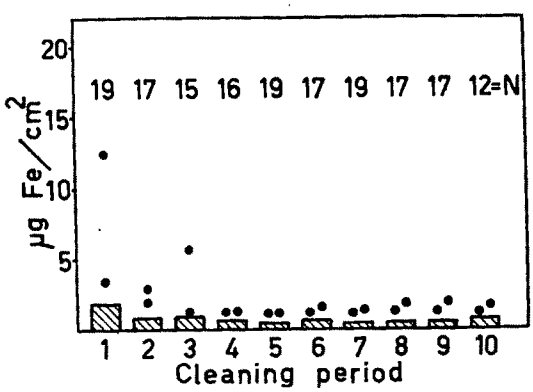

Fig. 2. Amount of iron dissolved out per ultrasonic cleaning period during standardization of specimen before corrosion experiment. N = number of determinations. Shaded areas indicate the mean values for each cleaning period

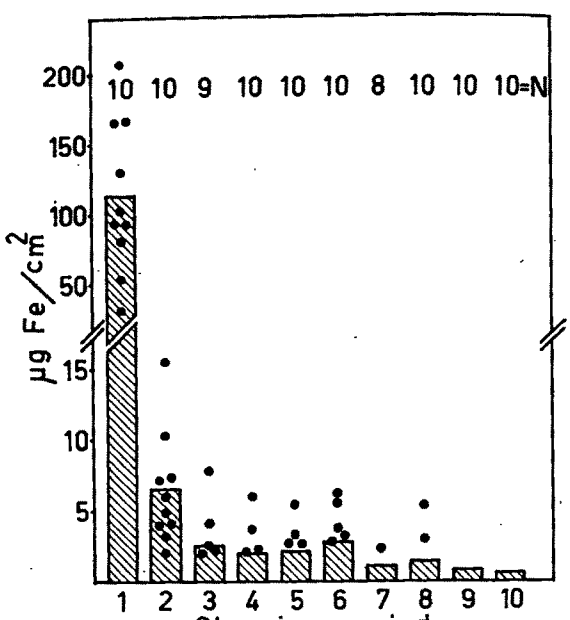

Fig. 3. Amount of iron dissolved out per cleaning period for the ten samples in Fig. 2 which were subjected to corrosion by steam treatment alone. The specimen rods were chosen at random. Shaded areas show the mean values and the points the individual values which exceeded 2 µg/cm². N = number of determinations. Amount of iron in the cleaning solution for cleaning period 1 includes also the corrosion products in the feed water

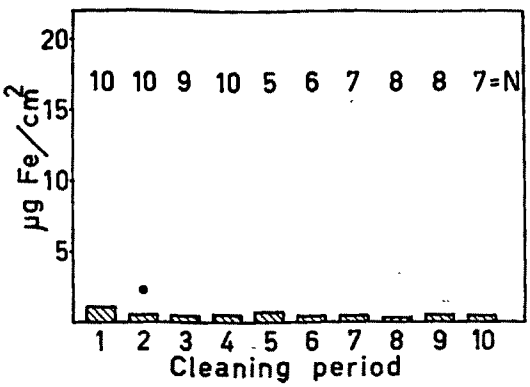

Fig. 4. Amount of iron dissolved out per cleaning period for the ten samples in Fig. 2 which were subjected to corrosion by steam together with 0·1 per cent *cyclo*hexylamine. The specimen rods were chosen at random. Shaded areas show the mean values and the points the individual values which exceeded 2 µg/cm². N = number of determinations

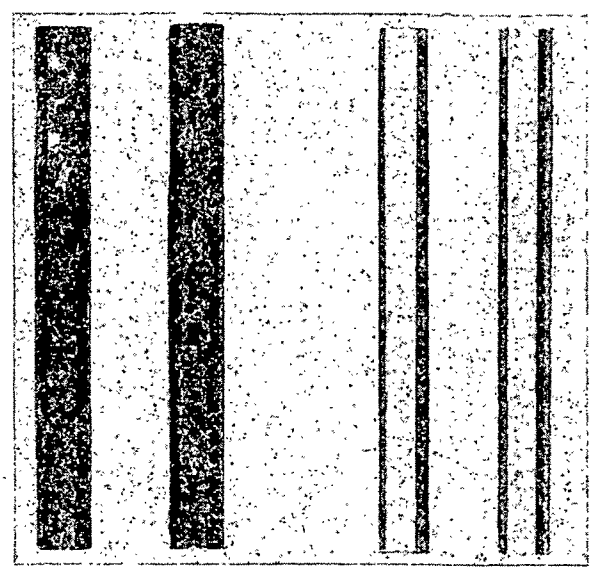

Fig. 5. Left, specimen rods subjected to steam and steam condensate; right, to the same corrosive medium but with *cyclo*hexylamine present as inhibitor. The specimen rods were cleaned ultrasonically in the manner described

hexylamine, practically no corrosion is obtained at atmospheric pressure even after applying steam and steam condensate at 98°–99° C for 120 min (Figs. 4 and 5) while steam and steam condensate by themselves give rise, under the same conditions, to a high degree of corrosion (Figs. 3 and 5). The experiments thus show that small, well-standardized specimen rods are suitable for corrosion studies of this type and that *cyclo*hexylamine is a volatile inhibitor possessing a considerable corrosion inhibiting effect in an atmosphere of steam. Moreover, they show that corrosion investigations can be carried out using short test periods provided that well-standardized experimental conditions and a sensitive method of measurement are used.

LETTERS TO THE EDITOR

ASTROPHYSICS

Distinguishing between the Solar, the Interplanetary and Geomagnetic Fields

In a paper[1] to be published I derive the number density (n) distribution of particles trapped in a magnetic tube of force specified only in so much as the speed and the magnetic moment of each such particles are invariants. The derivation extends and amends that of Dowden[2]. The density distribution is made to relate to that at a point (denoted by a prime) where the number density per steradian is isotropic or nearly so. Collisions and external forces are neglected. It is found that at a part of the tube where $B > B'$, $n = n'$ and where $B \ll B'$:

$$n \approx KB \qquad (1)$$

where K is constant.

It follows that different tubes of force are distinguishable by different K values.

Smith[3] and others used the empirical relation:

$$f_c^2 = af_H \qquad (2)$$

(where $a \approx 10^6$ c/s) to describe the whistler medium of the Earth, where f_c is the plasma frequency and f_H the gyrofrequency of electrons. This is equivalent to equation (1) so that $K = a/4\pi ce$. Thus for the Earth $K \approx 10^4$ cm^{-3} gauss^{-1}.

Assuming a dipole coronal magnetic field of 1 gauss at the Sun, Ingham's[4] distribution of electron density in the outer solar corona implies a value of $K \approx 10^7$, or $a \approx 10^9$ for the corona. My assumed value of magnetic field, however, may be inappropriate for the corona.

Using a value of $B = 10^{-4}$ gauss for the interplanetary field near the Earth and $n = 1$, $K \approx 10^5$ and $a \approx 10^7$.

It is suggested then that geomagnetic field may be distinguished from interplanetary field by measurement of either the pair (n, B) or the pair (f_c, f_H). Likewise interplanetary field may be distinguished from solar field. The distinction may be difficult if irregularities exist in the fields, for it may be expected that the K value for any particular tube of force could differ from the mean for its parent magnetic field. It would be interesting to know whether the magnetic field at 1 A.U. from the Sun is part of the solar field.

PHYSICS

Pressure Temperature Projection of the Three-phase Line of the Gallium Antimony System

Previous work has been carried out on the phase diagram of the gallium antimony system by several workers[1-3]. However, their work was limited to the composition temperature projection of the phase diagram.

The interest shown in the semiconducting properties of gallium antimonide[4] makes it desirable to grow stoichiometric single crystals. Crystals so far produced have, however, contained large numbers of electrically active impurities[4]. Since most workers grow their crystals with conditions such that antimony can freely evaporate, it is possible that this may be due to antimony deficiency[5].

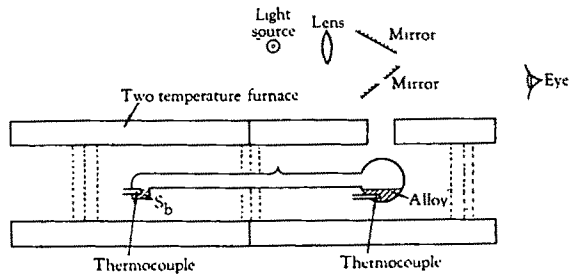

Fig. 1. Experimental apparatus

This communication describes an investigation undertaken to see whether the equilibrium pressure at the melting point was sufficiently large to cause this effect.

The apparatus used was very similar to that used for the Ga–Te system[6] and is shown in Fig. 1. The starting materials were zone refined GaSb and Sb. Before loading the materials were etched. (GaSb was etched with HF / HNO_3, 1 : 1 and the Sb with HCl / H_2O_2 / H_2O, 5 : 1 : 4.) The tube was evacuated and sealed off at a pressure of about 10^{-6} torr.

It was found that the alloys could be supercooled by up to 20° C so that only melting points were taken. The mode of operation was that the system was allowed to reach equilibrium for times of about 70 h just below the three-phase line. The melt temperature was then raised in about 3° C steps at intervals up to 24 h and the temperature at which the solid liquid transition occurred was noted.

Platinum–platinum 13 per cent rhodium thermocouples were used to measure the temperatures, which were computed from the thermocouple outputs using standard tables[7].

The results obtained are shown in Fig. 2, where they are plotted in terms of melt and reservoir temperatures. The pressures shown are taken from Honig's collection[8]. No attempt has been made to correct the reservoir temperatures for the effect of the pressure gradient in the tube. At the worst this would give a pressure correction of the form[9]:

$$\frac{P_A}{P_R} = \sqrt{\frac{T_A}{T_R}}$$

where P and T are pressure and temperature and the suffices refer to the alloy (A) and the reservoir (R). With

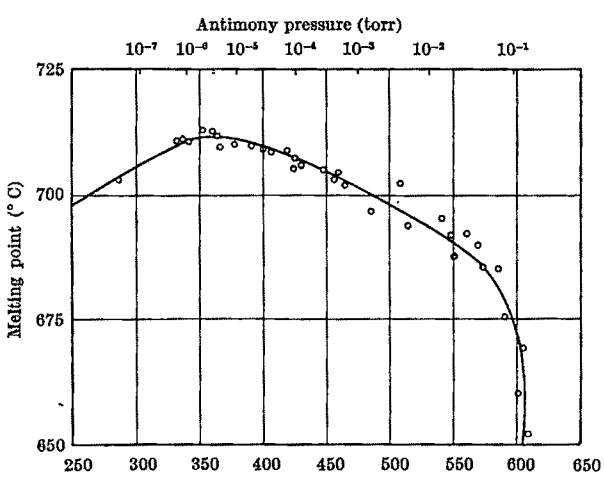

Fig. 2. Experimental results

T_A = 1,000° K and T_R = 600° K, P_R would be lower than P_A by about 30 per cent, which is equivalent to a 5° C correction to T_R.

Fig. 2 shows a maximum melting point of 712 ± 5° C, which is in reasonable agreement with the published values. At the maximum melting point the antimony partial pressure is (3 ± 1) × 10^{-6} torr (T_R = 360 ± 10° C). Depending on the diffusion coefficient, with this partial pressure up to about 2 × 10^{15} atoms per sec could be lost from each square centimetre of solid surface. This could lead to serious antimony deficiency.

British Standard of Radioactive Iodine-131

In 1952 it was agreed[1] to define the above standard in terms of the γ-ray dose-rate in air at 1 cm from a point source of 1 mc. of iodine-131. Such a procedure, utilizing a graphite ionization chamber, resulted at that time in greater precision and reproducibility than could be obtained by particle counting. It was estimated that the derived disintegration rate would not differ from the absolute value by more than ± 5 per cent.

Recently, the National Physical Laboratory, which is responsible for such standards in the United Kingdom, has issued certificates, in the case of iodine-131, giving disintegration rate values obtained both from ionization chamber measurements and from 4πβγ coincidence counting.

In future, standards will be based on the 4πβγ coincidence method since the inherent greater accuracy is now attainable. Activities quoted may be related to previous standards using a value for the ratio

$$\frac{4\pi\beta\gamma \text{ activity}}{\text{Ionization chamber activity}} \text{ of } 1{\cdot}024 \pm 0{\cdot}002.$$

Variation of Bed Height with Bubbling in an Air/Catalyst Fluidized Bed

During a preliminary investigation of mass transfer from bubbles in a fluidized bed composed of cracker catalyst (mean particle size 60μ), it was noticeable that the presence of bubbles caused a reduction of the height of the bed which was obtained when either a bubble flowstream or individual bubbles were injected into the bed. It appears that gas flows preferentially from the continuous phase into the bubble, and that the hold-up of gas in the continuous phase is reduced because the rising velocity of the bubbles is about 100 times that of the gas in the continuous phase.

The apparatus used for the investigation consisted of a 'Perspex' tube 9-in. diameter with a 'Vyon' distributor and beds of up to 60 in. deep could be accommodated. Preliminary results were obtained using either a single orifice ⅛-in. diameter at the centre of the bed, or three ⅛-in. diameter orifices placed symmetrically in the bed.

By injecting a single bubble, the bed was caused first to expand by an amount equal to the volume of the bubble. Immediately the bubble had left at the top, the bed collapsed to a point well below the initial height. Further, when the bed flow-rate was less than about 1·5 times the minimum fluidizing velocity, bubbles injected at flow-rates of up to 400 ml./min failed to reach the surface. Gas from the bubble was transferred to the continuous phase, and the height of the bed was slightly increased.

From the measurements of the reduction in height of bed it was possible to calculate the effective bed flow-rate and hence the amount of air transferred from the bed to the bubbles. Using either a single or a triple orifice for a given total bubble flow-rate, the rate of air removal from the bed was constant. Thus, within limits, the method of bubble formation had no apparent effect.

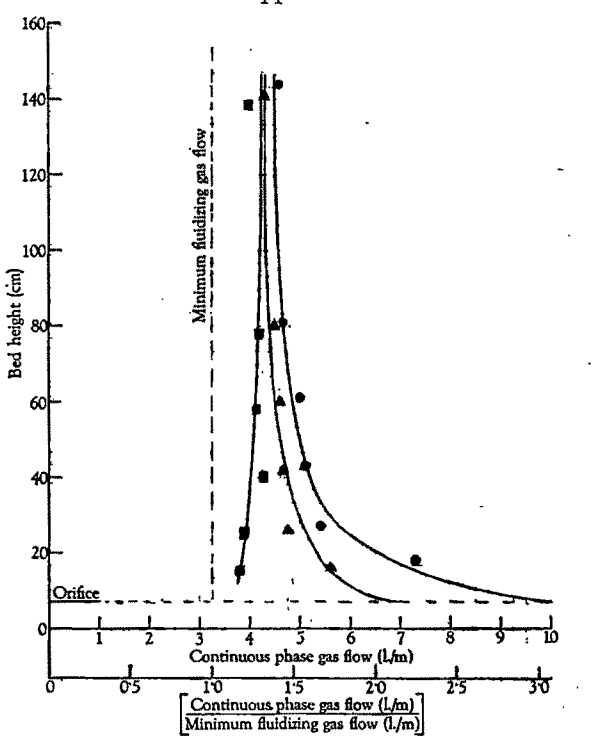

Fig. 1. Injected bubble flow-rate 240 l./m. ●, Initial bed flow-rate 10·0 l./m; ▲, initial bed flow-rate 7·0 l./m; ■, initial bed flow-rate 5·0 l./m

The results of experiments carried out at one particular rate of injection of bubbles into the bed are shown in Fig. 1. The rate of flow of gas in the continuous phase at equilibrium is plotted against height of bed for a range of initial bed flow-rates. It will be noted that, in all cases, the curves tend at large bed-heights to a constant value. The transfer is most rapid immediately above the orifice and the limiting value can be approached from either direction.

Microwave Inversion Efficiency of Orange Ruby

Recently some ruby, grown by a vapour-phase process, has been found to be orange coloured rather than the normal pink. Some of this has been investigated as a potential maser material by taking a small sample (~10 mg), containing 0·05 per cent Cr^{3+}, double pumping

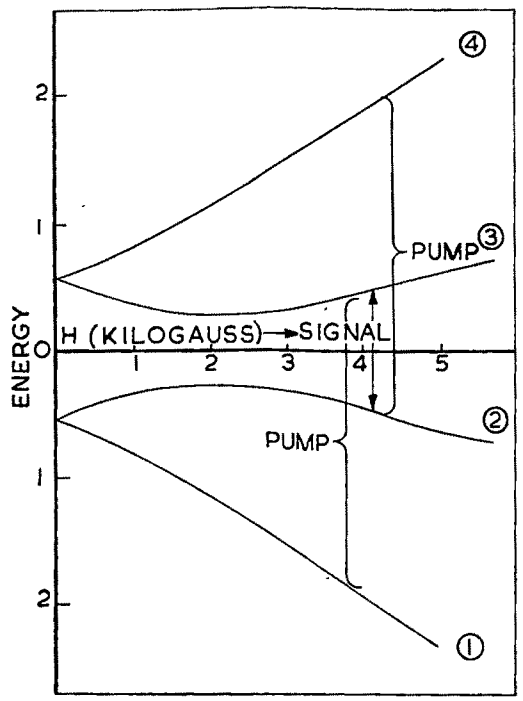

Fig. 1. Energy-levels of Cr^{+++} in ruby. Magnetic field at 54° 44′ to C-axis (energy expressed in kMc/s)

at 23 kMc/s and observing the resulting inversion of the 2–3 transition at 9 kMc/s (Fig. 1). This was then compared with the inversion obtained from a sample of pink ruby of similar size and concentration, placed in the microwave cavity, alongside the orange ruby. The c axes of the two crystals were arranged to be at 90° to each other and at 45° to the radiofrequency magnetic field in order to achieve similar transition probabilities. The inversion ratio I, defined as:

$$I = \frac{\text{peak inversion}}{\text{peak absorption}}$$

when measured at 1·4° K, was found to be 1·5 for the pink ruby, while that of the orange was much bigger, being of the order of 5·0 for most samples.

The paramagnetic spectrum of the orange ruby shows the normal Cr^{3+} lines and also a broad line ~200 gauss wide with $g \doteqdot 2$, which is almost isotropic with respect to magnetic field direction. Measurement of the Cr^{3+} in alumina energy-level diagram[1] shows that the broad line is coincident with the idler transitions, 4–3 and 2–1, when the crystal is being operated in the double pump position. It is thought that this produces a rapid relaxation path between levels 4–3 and 2–1, thus producing an enhanced inversion between levels 3 and 2, a process very similar to that used in the first successful maser[2].

Chemical analysis of this orange ruby has not as yet revealed any appreciable quantities of chemical impurities. It is thought that this broad line originates either from a valence state of chromium other than Cr^{3+}, possible Cr^{+} which has a $^6S_{5/2}$ ground-state, or from some colour centre formed in the vapour phase process due to unusual flame conditions. Some undoped corundum, grown by this method, is now being examined for colour centres.

It would appear that this orange ruby is worth further investigation as it may prove to be superior to the normal pink ruby as maser material. We hope to carry out some inversion measurements at liquid nitrogen temperature to see whether relaxation times remain favourable for an enhanced inversion at higher temperatures.

We thank Thermal Syndicate, Ltd., Wallsend, for supplying the ruby, and the Chemical Inspectorate, War Office, Woolwich, for the chemical analyses of the specimens.

METEOROLOGY

Effect of Carbon Dioxide on Evaporation of Water

As meteorologists probe more deeply into the physical processes involved in the growth of cloud droplets, they are rapidly led to a conclusion which physical chemists have appreciated for quite some time: the varied and unique properties of ordinary water suggest a highly complex structure much of which still remains obscure. On this point there is little disagreement. There is considerably less agreement, however, on the best way in which to re-examine some of the classical concepts on which our facile and inadequate models of liquids are based. Evidence mounts that a fresh start must be made before we can obtain a realistic and fruitful working model. In this connexion, we have chosen to scrutinize the classical concept of evaporation.

Recently, Weyl (personal communication) suggested that the interaction of the overlying gas with the surface may tend either to facilitate or impair evaporation of the liquid, depending on the nature of the liquid or gas, respectively. Consequently, the nature of the overlying gas should influence the evaporation rate of water. According to Weyl, evaporation depends on the rate at which a polymerized liquid is changed into single molecules. Since such a rate is subject to catalysis, an overlying gas may serve as a catalyst in this reaction. Weyl predicted that carbon dioxide would cause an increase in evaporation rate of water, other conditions being equal. In view of this, an experiment was designed to test Weyl's hypothesis.

In order to test the effect of overlying gases on the evaporation rate of water, two identical 'Lucite' chambers were constructed to house shallow brass evaporation dishes 2 cm in diameter. Under uniform ambient conditions this would ensure equal evaporation from both dishes. The diminishing height of the water meniscus over the dishes filled with distilled water provided a measure of evaporation rate; the menisci were optically projected on to a grid on which the lowering of the meniscus apex was recorded every 15 or 30 min, depending on the evaporation rate, for periods of 3–4 h.

Initially, one chamber was ventilated with carbon dioxide, the other with air. The water sample in the chamber containing carbon dioxide was observed to evaporate most rapidly. Efforts were made to regulate the flow of the gas by use of flow meters but it was felt that it would be extremely difficult to provide equal ventilation due to differences in temperature and density of the gases involved. Also, significant amounts of carbon dioxide were observed to become dissolved in the water of one chamber. No bubbles were observed to migrate to the surface. The stable bubbles of carbon dioxide that formed on the bottom of the dish suggested that the effect of the gas on the evaporation rate could be examined by bubbling carbon dioxide through the distilled water before placing it in the chamber and omitting ventilation of the chamber. Thus, the effect of dissolved carbon dioxide on the evaporation rate of water could be compared with the evaporation rate of water free of carbon dioxide. A variation of this experiment consisted of

saturating distilled water samples with hydrogen, helium, oxygen, nitrogen, and air, respectively.

As a result of fifteen sets of observations, the water containing the dissolved carbon dioxide consistently evaporated more rapidly than the control water sample. The increase in evaporation varied between 15 and 50 per cent. This was undoubtedly due to the fact that the amount of carbon dioxide dissolved in the water was not kept constant. The gas was bubbled through the water at various temperatures; since solubility decreases with increasing temperature one could expect a smaller effect at higher temperatures. This, in fact, was observed: when the temperatures were higher and the evaporation rates were also higher, the increase in evaporation rate due to carbon dioxide in solution was less.

On the average the measurements revealed a 30 per cent increase in evaporation of the water containing the carbon dioxide over the control samples. No significant difference in evaporation rates was detected when other gases were substituted for carbon dioxide. The results of these experiments suggest the desirability of continuing the investigation with more elaborate experimental design using various gaseous environments.

All possible experimental errors were scrutinized. First, it was suggested that the carbon dioxide escaping from the water surface would sink in the lighter environment of air and set up convection currents which would enhance evaporation of the water. To prevent this, carbon dioxide was introduced into the chamber so that buoyancy effects would be avoided. This did not alter the results reported here. Second, since carbon dioxide strongly absorbs infra-red radiation, we examined the possibility that the sample containing carbon dioxide would absorb more heat from the projector beam than the plain water sample and thereby evaporate faster. To test this, the projector lamp was turned on only for the very short periods of time required for recording the height of the meniscus.

The more rapid evaporation of the sample containing carbon dioxide continued. Third, to ensure that the control and test chambers were identical and that they were subject to essentially the same ambient conditions, many runs were made in which both chambers contained plain water samples. In each case, the evaporation rates were then the same.

Using the most pessimistic estimates of these and various other possible errors, I found that their influence on the evaporation rate is negligible when compared with the observed effect reported here.

Alignment of Cirrus Clouds along the Magnetic Meridian

Cirrus clouds appear very often in a regular array of parallel bands. Alexander von Humboldt[1] discovered in the course of his meteorological observations in South America and Siberia that these arrays follow frequently the line of the geomagnetic meridian of the locality; he invented the term "bandes polaires" for this phenomenon. Even very casual observations confirm the truth of his statement. He suspected some connexion between the appearance of these 'polar bands' and that of the aurora borealis. In the light of present-day knowledge of the composition of cirrus clouds, it is possible to put forward an explanation of this alignment. Since the constituent ice particles are known to form around dust particles of partly meteoric origin, they will align along the lines of force of the geomagnetic field in those cases in which the dust core consists of a magnetic material. It follows incidentally that the concentration of magnetic meteoric dust in the upper atmosphere should increase from the equator towards the poles, a hypothesis which is confirmed by Sobermann's[2] recent work on the composition of noctilucent clouds above northern Sweden.

Humboldt[3] observed, furthermore, that the alignment of cirrus clouds is more often seen and is of longer duration near the equator than in northern latitudes where their direction gradually changes from that of the magnetic meridian to an east–west line. This movement of the cirrus bands may be due to the action of the jet streams which occur at approximately the same height as cirrus clouds. It seems therefore that observations of the occurrence and movement of aligned cirrus bands may be of use in the investigation of the force and direction of jet streams.

GEOLOGY

F_2 Quartz Veining in the Manx Slate Series

The geological foundation of the Isle of Man is an aged, complex sequence of slates, flags and greywacke, termed the Manx Slate Series. This thick geosynclinal pile, apparently of Cambrian age, outcrops over the greater part of the Island.

Previous research by me[1] has demonstrated the polyphase structural history of the Manx Slate Series during the Caledonian orogeny. Three distinct episodes of tectonic movement (F_1, F_2, F_3) each formed large-scale folds, a suite of congruous minor flexures and an axial-plane cleavage (S_1, S_2, S_3).

The F_1 fold-system is characterized by steep, acute flexures and the accompanying S_1 is a flow cleavage in pelite. The subsequent F_2 and F_3 folds possess a more open, right-angled style, but are easily distinguished by their difference in orientation. The axial planes of the F_2 flexures are flat-lying or gently inclined while those of the F_3 generation dip steeply and consistently to the north-eastern quadrant. The related S_2 and S_3 are strain-slip cleavages. A syn-tectonic F_1 metamorphism produced the mild, chlorite-zone alteration which characterizes these strata[2].

Throughout the Isle of Man the plicated Manx Slate Series is traversed by conspicuous quartz-veining. Individual veins usually vary from a fraction of an inch up to several inches thick though instances measurable in feet are not uncommon. This veining only rarely accompanies the more severe F_1 deformation. The widespread injection of most of the white vein-quartz occurred during the second (F_2) movement-phase and is characteristically associated in the field with mesoscopic F_2 structures. The veining becomes particularly intense and abundant at loci where minor F_2 folding is severe, emphasizing its syn-kinematic nature. The most favourable host rocks are the uniform pelite of the slate formations and the thinly striped strata of the various banded groups. The veining is less abundant in flaggy units. In the Barrule Slates, the contrast between the dark pelite and the white quartz is particularly striking.

The F_2 quartz-veining adopts three main modes of occurrence controlled to a large extent by the time of emplacement during the F_2 movement. These are: (1) concordant veining; (2) discordant veining; (3) irregular veining.

Concordant veining was emplaced along either bedding or S_1, whichever was the dominant S-plane, during F_2 flexural-slip. After injection, such veining was later implicated in the crumpling and effectively outlines the F_2 contortions. In places the veining is cut by

the undeformed S_2 developed in the host rock during the later growth of the F_2 system by planar-slip.

Discordant veining was emplaced at a later stage in the F_2 movement along the already formed S_2 and therefore transects bedding and S_1. Small veins of this type have the form of thin, planar lenses with a lenticular cross-section. On a larger scale the quartz adopts the form of thick pods or augen which thin out rapidly towards their margins. A favourite site for these larger bodies, up to several feet thick, is along the axial planes of mesoscopic F_2 flexures.

Much *irregular veining* of F_2 age also traverses the Manx Slate Series with no regard for the pre-existing S-planes. The injection of such veining evidently took place throughout the F_2 movement. The earlier influxes are affected by F_2 crumpling and cut by S_2 while the later material is only disrupted by the cleavage. A proportion of the irregular veining, injected at the close of the second movement, anastamoses discordantly through all the F_2 minor structures.

The bulk of the quartz-veining in the Manx Slate Series is of F_2 age. Only small amounts were occasionally injected during the last (F_3) phase of folding. Such veining is restricted to sporadic localities where F_3 minor crumpling is more strongly developed than usual. In the south-western tip of the Island it has been observed along minor F_3 slides and may occupy tension gashes opened in competent quartzite by F_3 bedding-slip.

Source of the Glencoe Ignimbrites

Ignimbrites[1,2] are a characteristic component of the typically post-orogenic basalt–andesite–rhyolite volcanic association. These pyroclastic deposits are now generally accepted[2] as having been produced by eruptions of *nuées ardentes* in which solid particles, both rock and crystal fragments, glass shards and pumice fragments are suspended by turbulent flow in gas, probably derived in part from the glass shard and pumice material itself[3]. Such a fluidized system[4] forms the basal avalanche of a *nuée ardente*. While associated with several types of volcanic structure, most of those ignimbrite deposits with a volume greater than 10 km^3, and the source of which is known, have been related either to calderas or, for the larger volume (> 1,000 km^3) deposits, to volcano-tectonic depressions[3]. No intrusive igneous body has yet been recognized which, on clear-cut evidence, served as a feeder for extensive ignimbrite flows[3].

At Glencoe, Scotland, an approximately cylindrical mass of metamorphic rocks overlain by a thick pile of Lower Devonian volcanics subsided in two stages within ring-faults. During the cauldron subsidence the early and main Glencoe Fault Intrusions were emplaced as discontinuous ring-complexes up the ring faults[5]. Within the lava sequence, consisting largely of andesites and rhyolites, recent work by me has lead to the recognition of two thick ignimbrite sheets within Groups 2 and 5 (ref. 5). Both ignimbrites are rhyodacites, the lower being a lithic tuff rich in fragments of the underlying rhyolites and andesites, the upper a crystal tuff containing abundant felspar crystals. At the present level of erosion the lower horizon thickens towards the centre of the cauldron suggesting a caldera form at the time of eruption. The presence of Group 2 (ref. 5) rhyolite lavas and of Group 3 (ref. 5) volcanic conglomerates towards the margins confirms this view. The vulcanicity, rather than being "the quietly welling, effusive type", as originally thought[5], was explosive in nature.

Calderas are often the surface expression of the emplacement of ring dykes and complexes in depth by cauldron subsidence[6,7], accepted by most workers[7] as the product of magmatic stoping. Reynolds[4,6], however, has suggested that such complexes may be emplaced as fluidized systems of gas, solid fragments and, if the temperature is high enough, liquid droplets. On reaching the surface, this forms ignimbrite. Part of Reynolds's evidence[6] for fluidization comes from the published description[5] of the type locality of the main Glencoe Fault Intrusion at Stob Mhic Mhartuim, recently studied in detail by me. Here the porphyritoid facies of the fault intrusion is in contact with the downfaulted metamorphic rocks within the cauldron subsidence. The contact is marked by a narrow zone of "flinty crush-rock", originally interpreted as a product of frictional heat generated on the fault-surface during subsidence[5]. As Reynolds[6] suggests, in actuality it is an extremely fine-grained tuffisite formed by gas attrition of the conduit walls during the emplacement of the fault intrusion as a fluidized system. A similar contact is found against the country rocks outside the cauldron subsidence.

On this evidence it is suggested that the two ignimbrite horizons within the volcanic pile were derived respectively from the early and main Glencoe Fault intrusions during two periods of cauldron subsidence. The porphyritoid facies of the fault intrusions contains phenocrysts of plagioclase varying in composition from labradorite to oligoclase, hornblende, biotite and occasional pyroxene in a fine-grained felspathic matrix[5]. The ignimbrites show a more uniform composition. The crystal fragments present are predominantly oligoclase-andesine. Some quartz, not obviously of xenocrystal origin, is found in the upper horizon.

Ferromagnesian minerals, apart from occasional biotite flakes and rare pseudomorphs after hornblende, are generally absent. The ignimbrites thus appear to have been derived from the more acid varieties of the fault intrusion porphyrites, the hornblende and much of the biotite having been destroyed during their emplacement. Hornblendes and some biotites in the porphyrites are often rimmed by corrosion borders of magnetite dust and alteration products, formed by oxidation under near-surface conditions[8]. On eruption this process would be accentuated, producing the abundant magnetite dust now found in the ground-mass of the ignimbrites.

It is generally accepted that ignimbrites form by the explosive vesiculation of a glassy magma with the subsequent transport of the glass shards thus formed in a fluidized system, the pumice fragments representing the initial stages in this process[2]. Glass shard and pumice textures are not seen in the groundmass of the fault intrusion porphyrites but may have been destroyed by recrystallization. As the porphyrites are 'frozen' fluidized systems, pumice fragments may have been 'flushed' from the system during the earlier stage of flow. However, the lack of glass shard textures, which are generally retained despite recrystallization, suggests that liquid droplets, rather than glass shards as such, were originally present. On reaching the surface these would vesiculate by exsolution of gas to give glass shards. It may be that, towards the surface, the liquid droplets coalesce on the conduit walls to form a glassy layer afterwards disrupted to form the angular pumice fragments characteristic of ignimbrites[2].

CHEMISTRY

A Secondary Process in the Liquid-induced Crystallization of Polyethylene Terephthalate

It is known that amorphous polyethylene terephthalate may be crystallized by treatment with certain organic liquids[1]. With the polymer in the form of a film the process is accompanied by the appearance of opalescence, generally attributed to sub-microscopic spherulites, and is a function of time, temperature and film thickness[2]. In these investigations the thickness was at least equal to 2×10^{-2} cm. On extension of the work to include thinner films, it was observed that not only was there an increase of opalescence on treatment with a typical liquid such as acetone but also that after a certain time, afterwards referred to as an induction period, an almost opaque front was seen to move across the sample.

Use of reflectance and transmission microscopy indicates that the phenomenon is basically an internal one and involves a particulate structure, the size of the particles being of the order of a few microns. X-ray diffraction reveals no sharp distinction between samples which have undergone this change and those removed from acetone just before the process would have occurred. Figs. 1 and 2 show that the induction period is both temperature and thickness dependent, the latter suggesting that the reason why the phenomenon has not been previously noted, if it had taken place, was due in part to a high degree of opalescence which may have masked the process. Although it is premature to conclude a mechanism at this stage, it is suggested that it may be due to an internal fracture effect which occurs when the two main diffusion and associated crystallization fronts approach each other, abstracting amorphous material in two directions and resulting in a void in the centre of the sample. In this context it may be significant to note that it is found that the phenomenon does not apparently happen when diffusion is restricted to occur from one direction only.

We wish to thank Imperial Chemical Industries Ltd. for the polyethylene terephthalate film, and also to thank Mr. P. Blakey for assistance in the X-ray diffraction aspects.

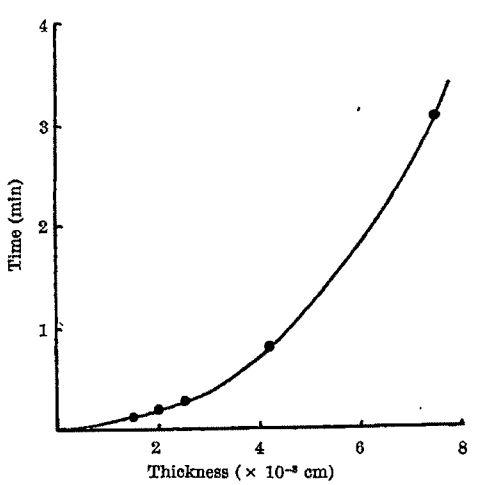

Fig. 2. Induction period versus film thickness

Solvated Electrons in Alkali Glasses

Evidence has recently been obtained which strongly suggests that 'solvated' electrons in water at room temperature have an absorption band in the 15,000 cm^{-1} region[1]. Jortner and Sharf[2] found a similar absorption in frozen aqueous solutions of alkali metal hydroxides at 17,000 cm^{-1} after exposure to 200 kV X-rays, which they attributed to trapped electrons, although they favoured an 'expanded' orbital on the cation as the trapping centre[2].

It has been suggested[3] that 'solvated' electrons, if such species exist, will not normally be produced by radiolysis of molecular solids since there is no opportunity for bulk reorientation of solvent molecules. However, if a frozen ionic solution were irradiated and anion vacancies could be generated by some means, then electrons could well be trapped as in *F*-centres to give the required 'solvated' electron centre.

Table 1. Details of that Feature of the Electron Spin Resonance Absorption Spectrum of γ-Irradiated Aqueous Sodium Hydroxide and Potassium Hydroxide Glasses at 77° K attributed to Trapped Electrons

System	*g* factor (± 0·0005)	Line width ± 1·0 gauss
10 molar NaOH in H_2O	2·0006	16·1
20 molar NaOH in H_2O	1·9995	18·5
10 molar KOH in H_2O	2·0005	11·8
20 molar KOH in H_2O	1·9997	11·6
10 molar NaOH in D_2O	2·0007	6·1
10 molar NaOH in 1 : 1 (by vol.) mixture of H_2O and D_2O	2·0009	11·8

We postulate that this is in fact the reaction observed by Jortner and Sharf, the hydroxyl ion being especially effective as an anion since it is the conjugate base of the solvent and can readily move, on demand, by proton migration. A systematic investigation of such systems by visible and electron spin resonance spectroscopy has been undertaken, and the results seem to support the model. Those features which are particularly relevant are summarized in Table 1 and will be briefly discussed.

There was no marked variation in the visible absorption spectrum with change in concentration of water or in the nature of the cation. On exposure to visible light the band in the 17,500 cm^{-1} region was lost, and a broad absorption in the near infra-red appeared. At the same time, one feature in the complex electron resonance spectrum of the γ-irradiated material was lost.

By subtracting the spin resonance spectra obtained before and after bleaching, an accurate plot of the absorption of the blue entity could be derived (Table 1). In most instances the absorption was symmetrical, and we direct attention especially to the following features:

(1) The line-width is greatly reduced on going from water to deuterium oxide.

(2) There is only a small cation dependence of the line-width, and there is no sign of any hyperfine structure from the cations.

(3) The g-values are almost independent of cation and are close to that found for solutions of alkali metals in ammonia and amines (about 2·0005).

These and other aspects of our results are in good accord with expectation for an 'F-centre' having water molecules rather than cations as the nearest neighbours, but they do not seem to be in accord with Jortner and Sharf's model[2].

The other paramagnetic species formed on γ-radiolysis has properties which suggest an O^- centre with strong environmental interaction. These results will be reported in detail elsewhere.

We thank the United States Department of Army (European) Research Office for financial support.

Mercuration of Diazomethane

As a possible route to *bis*-oxymethylmercury acetate, $Hg(CH_2CO_2CH_3)_2$, we have examined the reaction of diazomethane with mercuric acetate. Although a reaction has been stated to occur[1] no details of the products were reported. The reaction in ether was slow and heterogeneous. There was no evidence of methylenation of the mercury–oxygen bond, as apparently occurs with aryl-mercury benzoates[2], nor of reduction to mercurous acetate. Instead, when diazomethane (0·03 M) was slurried in ether with dry mercuric acetate (0·015 M), methyl acetate was formed (50 per cent after one day, 90 per cent after five days), together with an insoluble and dangerously explosive pale yellow solid (90 per cent), and small amounts of a soluble yellow oil. This oil, obtained by evaporation of the filtrate and separation from polymethylene on a short silica-gel column, is apparently *bis*diazomethylmercury, $Hg(CHN_2)$, analogous to the long known *bis*(carboxyethyldiazomethyl)mercury[3], $Hg(CN_2CO_2Et)_2$, although the yield (5 per cent) is much lower. It showed a strong localized absorption at 2,105 cm^{-1}, indicating a diazoalkane grouping, and evolved nitrogen with acids. Bromine decolorized it, giving mercuric bromide, nitrogen and some bromoform.

The solid (obtained by filtering and drying) was insoluble in all normal solvents except strong acids which detonated it. The infra-red absorption spectrum (mulls in medicinal white oil and 'Fluorolube') showed no evidence of alkyldiazo groupings, or of hydrogen attached to imide nitrogen or acetylenic carbon, and very little carboxylate. It is suggested that this material is formed by condensation of mercuric acetate with isodiazomethane to form a polymer $(-HgCNN-)_n$. Diazomethane can isomerize in the presence of base[4] and both imide nitrogen and acetylene groups mercurate readily. The infra-red spectrum showed strong bands at 1,960 and 1,710 cm^{-1}, suggesting a group containing cumulative multiple bonds, such as occur in allenes, azides and carbodiimides[5]. After reaction for 20 h, the infra-red spectrum of the precipitate indicated that carboxylate and imide groups were present, suggesting that the initial attack is at the acetylenic hydrogen rather than at the imide group, as with methyl lithium[4].

$$2CH_2N_2 \rightleftharpoons HCNNH$$

$$\downarrow HgAc_2 \qquad \downarrow HgAc_2 + CH_2N_2$$

$$AcHgCHN_2 + CH_3COOCH_3 \qquad AcHgCNNH + CH_3COOCH_3$$

$$\downarrow CH_2N_2$$

$$(-HgCNN-) + CH_3COOCH_3$$

This isodiazo structure is supported by the absence of this type of product when diazoethane and diazoacetic ester are treated with mercuric acetate, since they are not known to isomerize. With excess diazoacetic ester, *bis*(carboxyethyl-diazomethyl)mercury (m.p. 95°–98°, dec., from ether; lit. m.p. 104° dec.) was obtained in high yield. Similarly, diazoethane gave little insoluble material, apart from free mercury.

We thank Dr. R. A. Shaw (Birkbeck College, University of London) for his interest, and Miss J. P. Dixon for assistance.

BIOCHEMISTRY

Quantitative Spectrophotometric Determination of Indolyl-3-acetic Acid

Indolyl-3-acetic acid (IAA) can be determined either by non-specific biological methods[1] or by chemical methods[2]. Most of the quantitative work with auxins has been based on bioassays. This is probably due to their high sensitivity, and because larger amounts (300 g) of plant tissue are necessary to maintain precision when using chemical methods[3]. This communication describes a spectrophotometric technique which offers a means of precise, sensitive, quantitative estimation of IAA from small amounts of plant material.

'Free' auxins were extracted from the apical regions (including cotyledons) of *Phaseolus vulgaris*, var. Dutch Brown beans, using methanol as a solvent[2]. An aliquot of the crude extract representing 1·5 g fresh material was chromatographed on Whatman No. 1 paper and the identity of IAA confirmed by chromogenic reagents which included *p*-dimethylaminocinnamaldehyde (DMCA)[4]. The solvent was isopropanol/ammonia/water (8 : 1 : 1) and IAA was normally located by spraying a portion of the paper with DMCA. The corresponding R_F region (0·32 to 0·35) from the unsprayed portion of the paper was eluted with 3·5 ml. of methanol and the absorbance of the eluate between 230 and 300 mμ was measured using a Beckman *DK*1 spectrophotometer.

The absorption curve (Fig. 1*B*) obtained from the eluate of the region R_F 0·32–0·35 was identical in its characteristics with that of synthetic IAA (Fig. 1*A*). When the same procedure was followed with a greater quantity (3 g) of fresh material, resolution was unsatisfactory and contamination of the eluate occurred as evidenced by the

second absorption peak at 273 mμ (Fig. 1*D*). This was probably due to interference of an unknown compound obtained from R_F 0·29–0·32 (Fig. 1*C*). The contamination could, however, be eliminated either by the use of less material or by superior resolution, the latter being achieved by allowing the solvent front to flow off the paper.

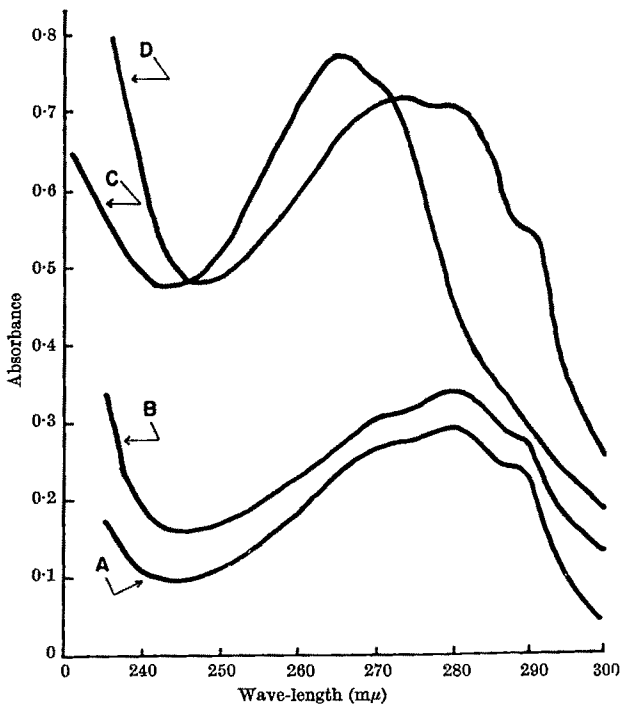

Fig. 1. Ultra-violet absorption curves. *A*, Synthetic IAA (10 μg/ml.); *B*, IAA (R_F 0·32–0·35) from 1·5 g fresh weight; *C*, unknown compound (R_F 0·29–0·32) from 1·5 g fresh weight; *D*, contaminated IAA (R_F 0·32–0·35) from 3 g fresh weight

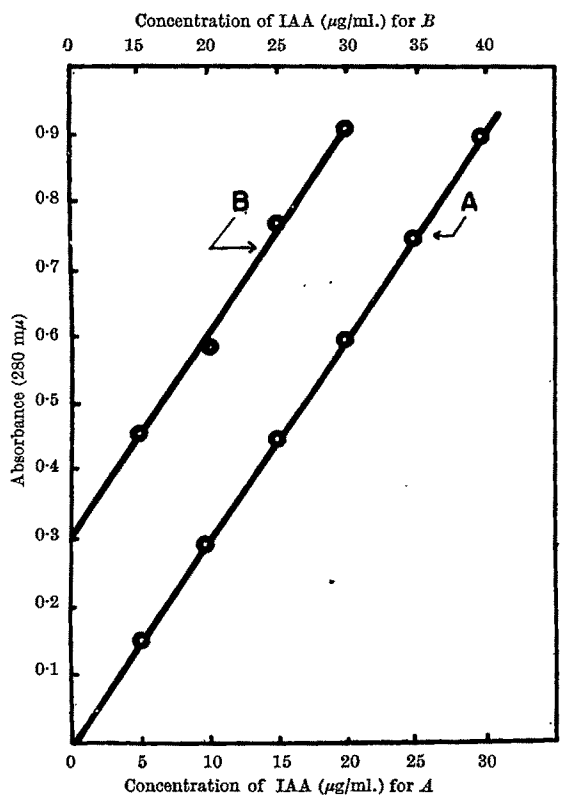

Fig. 2. *A*, Relationship between concentration and absorbance of synthetic IAA in methanol; *B*, IAA extracted from 1·5 g fresh material + 0, 5, 10, 15, 20 μg/ml. synthetic IAA

The absorption at 280 mμ of methanol solutions of synthetic IAA obeys Beer's law over at least the range of 1–30 μg/ml. (Fig. 2*A*). The sensitivity of spectrophotometric measurements was determined to be 0·2 μg/ml. at a concentration of 9–10 μg/ml. When known concentrations of synthetic IAA were added to the crude extract and the same isolation procedure followed, the absorption values of the eluate at 280 mμ were additive (Fig. 2*B*). A mean error of 1·1 per cent (of the mean concentration) was established using 10 replications of 1·5 g of fresh material.

The foregoing procedure represents a simple method for the qualitative and quantitative determination of IAA in extracts from relatively small amounts of plant material. Although this method is somewhat less sensitive than a bioassay it has the advantage of greater simplicity, precision and specificity.

A New Reticuloendothelial System Stimulating Agent ('Restim') from Shark Livers

We have previously reported a reticuloendothelial system stimulating agent ('restim') derived from cell walls of yeast[1]. The purpose of the present communication is to describe briefly a similarly active material composed of lipid derived from shark livers.

A variety of sharks were caught in the Gulf of Mexico. These included: lemon (*Negaprion brevirostris* (Poey)), nurse (*Ginglymostoma cirratum* (Bonnaterre)), (great) hammerhead (*Sphyrna mokarran* (Ruppell)), (lewin) hammerhead (*Sphyrna lewini*), black nose (*Carcharhinus acronatus* (Poey)), bull (*Carcharhinus leucas* (Muller and Henle)), tiger (*Galeocerdo cuviere* (LaSueur)), brown (*Carcharhinus milberti* (Muller and Henle)), dusky (*Eulamia obscura* (LaSueur)).

Previous experience indicated that species, sex, age, and season of the year may play a critical part with regard to the presence of any specific lipid in elasmobranch liver. In the case of the substance we sought—designated 'restim-*S*'—sex and age made no difference. Lemon, tiger and hammerhead sharks gave high yields. (Season of the year cannot be adequately evaluated, for many species are caught only in certain months in specific areas.)

The lipid which is active begins to deteriorate within 15–20 min after the shark's death. Sharks which have been dead for longer periods are not used. It has been our convention to bring the sharks in alive and kill them at once. The livers are removed. Blood and bile are rapidly drained out of the elongate lobes. The liver is cut into chunks and immersed in cold absolute ethanol for 30 min. The liver is then removed and packed in frozen carbon dioxide and shipped from the Gulf of Mexico to this Institute. Very often these livers, instead of being light yellow-brown, appear much darker and exhibit dark brown or almost black mottling. According to Dr. Ross Nigrelli of the New York Aquarium (personal communication), this is not an infrequent concomitant of stress. Such livers manifest both glycogen and fat depletion, and the discoloration is presumably ceroid and hæmosiderin. Such livers are not used.

One kilogram of fresh shark liver is homogenized in a blender with 2 l. of absolute ethanol. This homogenate is then diluted with 1 l. of ether and 250 ml. of hexane, and then allowed to stand for 2–3 h. It is then filtered. The freshest liver gives the most active lipid; but, because of its freshness, one extraction will not remove all the lipid. Therefore, the extraction procedure is repeated by taking up the wet residue in 1 l. of ethanol, 1 l. of ether and 250 ml. of hexane. It is then filtered once more, the residue discarded, and the solvents are removed *in vacuo*. The concentrate is then taken up in hexane and the hexane layer is filtered through anhydrous sodium sulphate. The hexane is then removed under vacuum, and the remaining lipid is dissolved in anhydrous ether. The ether solution is then treated with five volumes of cold acetone, and the mixture is kept in the freezer at −28° C for 24 h. After centrifuging at −2° C, the yellow acetone-rich supernatant is discarded. The residue is transferred into a flask with anhydrous ether. The ether is removed by distillation, and the lipid is stored at − 28° C under nitrogen. The yield is about 20 per cent by weight of wet shark liver.

This lipid is still only partially purified in this form but quite active in stimulating phagocytosis by the carbon clearance technique. Further purification is obtained by fractional crystallization. The chemically fractionated material obtained is put through a silicic acid column. A colourless, odourless, active fraction is thereby separated from inactive fractions. This is more stimulatory on phagocytosis than the crude lipid by a factor of 3- to 4-fold. The experiments reported herein are with the partially purified 'restim-*S*'.

For intravenous injection, the lipid, 5 mg/ml., is emulsified in 5 per cent glucose containing 0·025 per cent 'Ninol' (Stepan Chemical Co., Chicago, 6, Illinois). The particle size of the lipid emulsion is less than 1–2μ. This is important in the prevention of lipid microemboli.

Standard rabbit pyrogenicity investigations showed no significant temperature rise over a 6-h period with an intravenous dose of 350 mg per rabbit.

Determination of the effect of the partially purified shark lipid restim on non-specific and specific resistance of mice to challenge by *Salmonella typhimurium*[1] was made in the following manner. A pool of 60 mice was divided into six groups of 9–10 mice each. All mice used were males, weighing 20–25 g each at the beginning of the experiment. Group 1 received 'restim' 3 days before vaccination with 0·2 ml. of 1 : 1,000 stock vaccine[1]. 'Restim' was given intravenously, 1 mg suspended in 0·2 ml. of 5 per cent glucose. Fourteen days after immunization, an identical dose of 'restim' was given.

Group 2 mice received identical treatment except that the second dose of 'restim' was omitted. In the case of Group 3, the initial dose of 'restim' was omitted. Group 4 received vaccine only, Group 5 received both doses of 'restim' but no vaccine, and Group 6 received neither 'restim' nor vaccine.

On the twenty-third day following the first 'restim' dose (19 days post-immunization), all mice were challenged simultaneously with 0·2 ml. of a suspension of *S. typhimurium*, determined by plating to contain 3×10^6 viable bacterial cells. Deaths were observed daily for 20 days.

Fifty per cent survival with 95 per cent confidence limits were determined by Litchfield's method[2]. These data, together with percentage mortality, are given in Table 1.

The data indicate that the crude 'restim-*S*' alone neither prolonged life nor increased survival. An increase in 50 per cent survival and in survivorship was shown for all mice receiving the vaccine, as would be expected. When 'restim' was given in addition to vaccine, further increases, particularly in survival time, were demonstrated. Optimum results in increase of survival time were obtained with two doses of 'restim', although the best result for increased survivorship was obtained with one post-vaccinal dose of 'restim'. The statistical significance of this result, however, is doubtful. The data reflect similarity to results obtained with 'restim' derived from yeast[1].

Table 1. Effect of Shark Lipid 'Restim' on Survival Time and Survival in Mice challenged with Two 1,000,000 LD_{50}'s of *S. typhimurium*

Treatment	SD_{50} (95% conf. lim.)	% Survivors (20 days)
'Restim' 1 dose before and 1 dose after vaccine	16·5 (10·9–24·9)	40
'Restim' 1 dose before vaccine	10·5 (7·25–15·2)	33
'Restim' 1 dose after vaccine	8·6 (6·4–11·5)	60
Vaccine only	8·0 (6·0–10·6)	30
'Restim' only, 2 doses	2·4 (2·2–2·7)	0
No treatment	2·2 (1·9–2·5)	0

A New Metabolic Regulator: its Stimulation of Citric Acid Production and Anti-sulphonamide and Streptomycin Effect

Although at present many data are available concerning the production of citric acid by fungi[1–5], very little is known of the mechanism by which the production of this acid is regulated. Its production in *Aspergillus niger* varies greatly with the strain and the medium[6,7]. The same strain, under various conditions, is capable in one case of converting practically all the sugar available into citric acid; in another case production is decreased by the conditions of the reaction practically to zero.

From the foregoing, it follows that a regulation system exists which controls the utilization of sugar either in the direction of citric acid synthesis or in the direction of biomass production and respiration.

In searching for such a system, we have succeeded in obtaining from the fungus a substance which stimulates citric acid synthesis, and regulates its production (regulator *C*). Regulator *C* may be obtained from various strains of *Aspergillus niger*, and similarly from *A. terreus*. The method of isolation has already been described[8].

Although we have not yet succeeded in isolating regulator *C* in the pure state, we conclude from its properties that it is acid in character, stable at elevated temperatures, capable of dialysis, unstable in alkalis, practically insoluble in lipophilic solvents. Fig. 1 shows the effect of regulator *C* on the production of citric acid for several strains of *Aspergillus niger*, on synthetic and molasses-containing substrates, for a nine-days old surface culture. The *K* 10 strain is a production strain on molasses; in the case of the other strains there are no marked differences between production on synthetic and molasses-containing substrates. The regulator has increased production in all cases, even when production was relatively high as, for example, in the case of the *K*10 strain on molasses.

It has been proved at the same time that regulator *C* does not influence the rate of citric acid decomposition in the case of this fungus.

In further work, the effect of the regulator *C* on the formation of citric acid by ground mycelium has been examined. Mycelium was ground first on a propeller-type mixer, and the operation was finished in an instrument devised by Nossal[9].

The regulator was first separated from the mycelium by means of dialysis. Citric acid formation occurs only in the ground material to which the regulator has been added (Fig. 2). The regulator slows down production of other acids, and synthesis is oriented only in the direction of citric acid formation.

Table 1. Influence of Regulator *C* on the Growth of Micro-organisms

Micro-organism	Inhibitor	Regulator	Turbidity
Streptococcus faecalis	*p*-Toluene sulphonamide 1×10^{-2} moles		
	–	–	1·13
	–	+	2·25
	+	–	0·20
	+	+	1·15
	p-Aminomethyl benzol-sulphonamide 1×10^{-2} moles		
	+	–	0·50
	+	+	1·17
	Streptomycin 10 μg/1 ml.		
	+	–	0·20
	+	+	1·20
Escherichia coli	–	–	1·89
	–	+	2·70
	+	–	0·68
	+	+	2·05

Growth on Bouillon medium has been evaluated turbidimetrically. Measurements were carried out after 24 h of cultivation at 36° C.

It is known from the literature that sulphonamides inhibit very intensively the production of citric acid[10]. According to our experience, this inhibition can be proved only for some strains of *Aspergillus niger*. We have shown that regulator *C* is able to reverse this inhibition, and that even its stimulating effect can be manifested, so that citric acid production is higher than for the control. *p*-Aminobenzoic acid does not have these effects (Fig. 3).

Coenzyme A, which is assumed to be necessary for citric acid synthesis[11,12] and the function of which is, according to Indian authors, inhibited by sulphonamides, has neither been found capable of stimulating production, which agrees with earlier results[13], nor of eliminating the effect of sulphonamides.

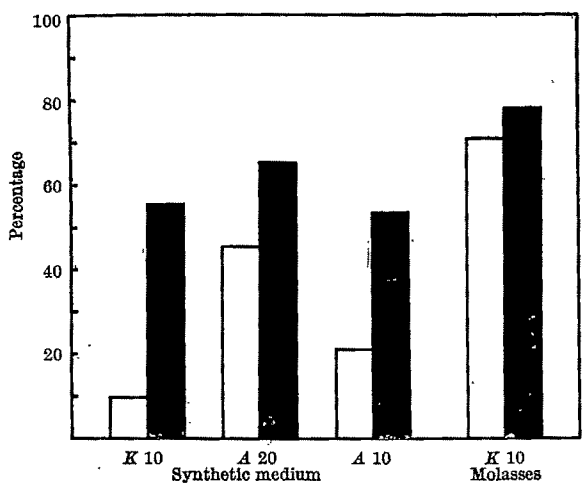

Fig. 1. Influence of regulator *C* on citric acid production, which is plotted as percentage of sugar introduced on the *y* axis. *K* 10, *A* 10, *A* 20 *Aspergillus niger* strains. The first columns express production-levels in control flasks, the second columns express the same value after addition of regulator *C*

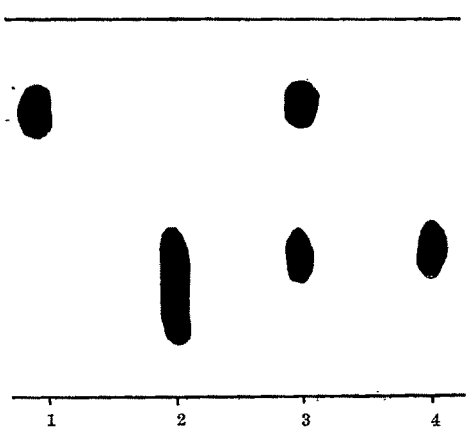

Fig. 2. Production of citric acid by ground mycelium. 1, Citric acid sample; 2, broken mycelium without addition of regulator *C*; 3, citric acid synthesis after addition of regulator *C*; 4, regulator *C*

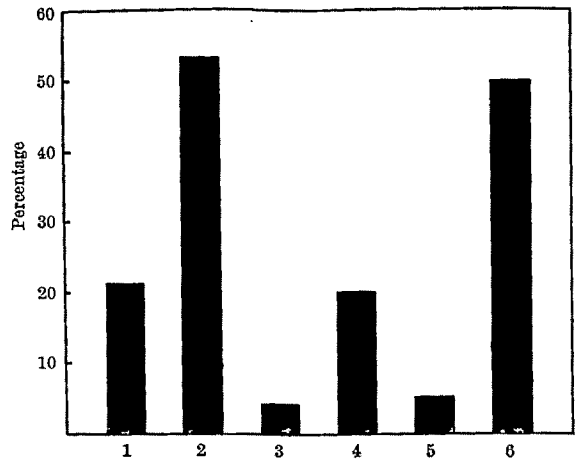

Fig. 3. Elimination of the inhibitive influence of sulphonamides on citric acid production. This production is plotted as a percentage of sugar introduced on the *y*-axis. 1, Citric acid production in the control; 2, citric acid production after addition of regulator *C*; 3, citric acid production after addition of *p*-toluenesulphamide at a concentration of 7×10^{-4} moles; 4, citric acid production after addition of *p*-aminobenzoic acid; 5, citric acid production after addition of *p*-toluenesulphamide and *p*-aminobenzoic acid; 6, citric acid production after addition of *p*-toluenesulphamide and regulator *C*

With regard to the fact that regulator *C* is capable of eliminating the effect of sulphonamides, its effect on the growth of bacteria has been investigated, especially on *Streptococcus faecalis* and *Escherichia coli*. We have found that the regulator substantially stimulates the growth of these micro-organisms, and further that it eliminates the inhibitive effect of sulphonamides and streptomycin on the propagation of these microbes (Table 1).

We have adopted several methods of purifying regulator *C*, and we have tested the preparations obtained with regard to their effect on the production of citric acid, the growth of microbes and the elimination of the effect of streptomycin. We did not, however, succeed in finding any difference in the efficiency of these preparations in the aspects named. This shows that the effects are due probably to the same regulator.

The results of earlier work[6] and of these experiments permit the conclusion that the high production of citric acid by fungi is independent of the formation of a new enzymatic system in the mycelium, as well as of the inhibition of its decomposition, but that it depends on the presence of a regulator, which in the function of a coenzyme controls sugar metabolism in the direction of citric acid production. Its effect on the growth of micro-organisms and the antagonistic influence on sulphonamides and streptomycin, furthermore, show that the substances, or several substances of which the regulator consists, have a more general function in the metabolism of micro-organisms.

In vivo Degradation of Histamine-adenine Dinucleotide Phosphate to Histamine Ribonucleoside

ENZYME-CATALYSED interactions of histamine with pyridine coenzymes, leading to formation of histamine-substituted dinucleotides, were previously observed in our laboratory[1–3]. These findings were later confirmed by Muraoka *et al.*[4,5] and Devi *et al.*[6]. In more recent experiments, 2^{14}C (ring)-labelled histamine was administered to guinea pigs[7], or it was incubated with mast cell preparations[8] and guinea pig lung mitochondria[9]. In all experimental set-ups, after deproteinization of the homogenized carcass or the incubation mixtures, carrier (non-labelled) histamine dinucleotides were added to the supernatant. After re-isolation and repeated (up to 15 times) purification by alternative ionophoretic and chromatographic procedures, the dinucleotides were examined for radioactivity (autoradiography). By this procedure, traces of *de novo* biosynthesized dinucleotides were invariably detected. In addition, however, unidentified labelled product(s) appeared during the isolation procedures. On the assumption that histamine-adenine dinucleotides are rapidly degraded in the body or in tissues, we recently studied the fate of histamine-adenine dinucleotide phosphate (structurally: histamine-ribose-pyrophosphate(ribose-2′-phosphate)adenine) after intraperitoneal injection of the labelled compound in mice and guinea pigs. This is a preliminary account of our findings in mice.

Young adult male mice (about 25 g) of either the *AKR* or the Swiss strain were used in these experiments. Ten to twenty μmoles of 2^{14}C(ring, histamine)-labelled histamine-adenine dinucleotide phosphate[3], with specific radioactivity of 30,000–50,000 c.p.m. per μmole counted in a windowless flow-counter, were dissolved in 1 ml. of sterile 0·15 M sodium chloride and injected intraperitoneally. Amounts of total radioactivity excreted in the urine of an *AKR* mouse are shown in Table 1. Aliquots from the first day's collection of urine were run ionophoretically[2] at *p*H 7·9 along with appropriate 2^{14}C(ring, histamine)-labelled controls (Fig. 1). The radioactive material from the urine moved towards the negative electrode at the same rate as did histamine ribonucleoside prepared *in vitro* through the consecutive action of nucleotide pyrophosphatase and 5′-nucleotidase[2,10]. The radioactive spot from urine was ninhydrin-positive and, after elution from the paper, part of this material was subjected to acid hydrolysis in a sealed tube (2 N hydrochloric acid, 2 h, 115°). Only after this treatment did the eluate from the paper react in the orcinol test for ribose[11] and coupled with diazotized sulphanilic acid[12], indicating the liberation of ribose and histamine. This is in harmony with previous findings regarding the behaviour of the histamine-ribeos bond to acid hydrolysis[13]. The material in the eluate was free of (esterified) phosphorus[14]. Larger quantities of purified histamine ribonucleoside were obtained from two-dimensional paper chromatograms of the urine. In the first dimension, the chromatogram was developed in 80 parts *n*-butanol, 10 parts 95 per cent ethanol and 30 parts concentrated ammonia[15]. Separation was achieved by development in the second dimension with 0·025 M formic acid/ethanol, 1 : 1. The radioactive material moved as a single band and behaved as did the *in vitro* prepared histamine ribonucleoside. Preliminary evidence indicates that histamine ribonucleoside is also a product of histamine-adenine dinucleotide phosphate metabolism in the guinea pig.

The foregoing results confirm previous *in vitro* observations[5,10], which indicated that histamine ribonucleoside or histamine-adenine dinucleotides were not substrates for oxidative deamination. They are also in agreement with

Table 1. EXCRETION PATTERN OF RADIOACTIVE MATERIAL IN THE URINE OF AN *AKR* MOUSE AFTER INTRAPERITONEAL INJECTION OF 2^{14}C(RING, HISTAMINE)-LABELLED HISTAMINE-ADENINE DINUCLEOTIDE PHOSPHATE

Time (h after injection)	Vol. collected urine (ml.)	Total c.p.m.
24	0·6	477,000
30	0·2	58,000
46	0·7	6,335
54	0·2	470

Male *AKR* mouse of 25 g body-weight; 17·4 μmoles of 2^{14}C(ring, histamine)-labelled histamine-adenine dinucleotide phosphate of specific radioactivity of 34,000 c.p.m. per μmole; other conditions as described in the text. Data from ref. 10.

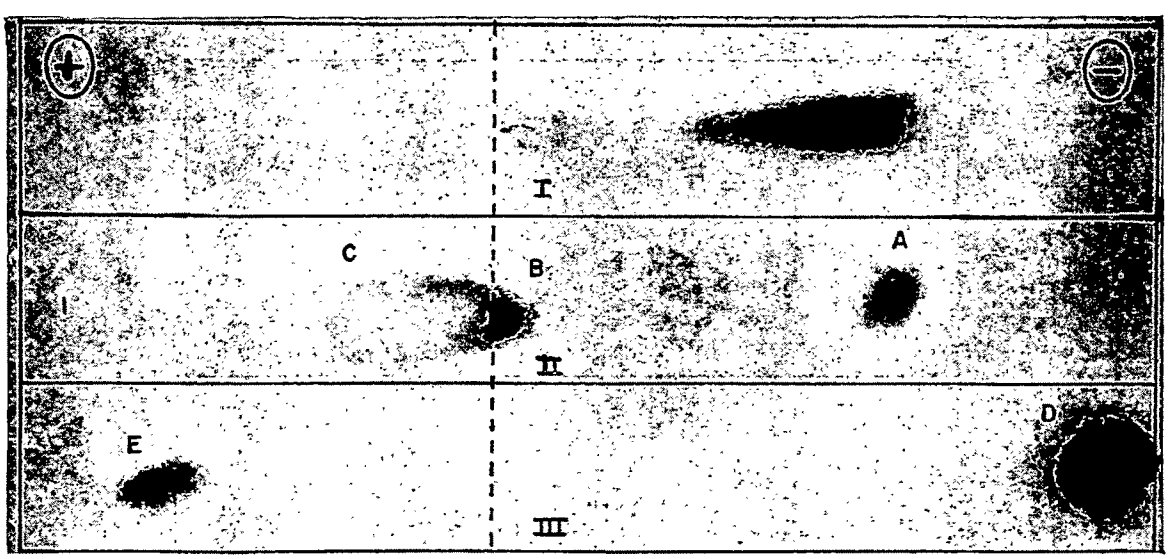

Fig. 1. Relative positions of histamine-adenine dinucleotide phosphate and other 2^{14}C-(ring, histamine)-labelled compounds in a paper ionopherogram. *Tris*-HCl buffer at *p*H 7·9, specific resistance 200 ohms at 4° C, 62 V h per cm. Other conditions as described previously (ref. 2). Spots were applied along the dotted vertical line.

Horizontal line No. I. Aliquot from the first day's collection of mouse urine (see Table 1). Longer exposure to the X-ray film (see below) revealed no additional spots. The longer dimensions of this spot may be due to the salt content of the specimen (urine), although the presence of two closely related compounds cannot be excluded at present.

Horizontal line No. II. Aliquot from an *in vitro* incubation mixture of histamine-adenine dinucleotide phosphate with a partially purified preparation of nucleotide pyrophosphatase from *Crotalus adamanteus* venom (ref. 20) and 5′-nucleotidase (ref. 21). In addition to histamine ribonucleoside (*A*), this mixture contained histamine-adenine dinucleotide (*B*), most probably derived from histamine-adenine dinucleotide phosphate by the action of a 2′-nucleotidase present as a contaminant in the snake venom preparation, and an as yet unidentified product (*C*) (probably histamine ribonucleotide).

Horizontal line No. III. Aliquots from chromatographically purified solutions of histamine (*D*) and histamine-adenine dinucleotide phosphate (*E*) (ref. 3). Spots developed by contact radioautography with Kodak 'No-Screen' medical X-ray film. This photograph is a composite of which horizontal lines I and II of the ionopherogram were exposed to the film for 14 days, while horizontal line No. III was exposed for 3 days. Spots *B* and *E* were also visible under ultra-violet light with a 'Mineralight *SL* 2537' lamp

the view that formation of a histamine-ribose bond represents a catabolic process[16] and it is not involved in the mechanism of histamine release, as proposed by Yamasaki *et al.*[17]. Conclusions similar to ours were also recently reached by Muraoka *et al.*[5] on the basis of *in vitro* studies. According to preliminary evidence which appeared a few years ago[16], histamine ribonucleoside may also be formed by enzymatic interaction of histamine with 5-phosphoribosyl-1-pyrophosphate. However, these findings have not been confirmed as yet in our laboratory. Thus, it is possible that histamine dinucleotides are the sole source of histamine ribonucleoside in tissues of adult animals[19]. In view of this, search for the ribonucleoside among the excretion products of histamine, especially in correlation to the animal species and to the particular state of sensitization of the animal, might prove of considerable interest.

Occurrence of Two Different Enzymes in the Silkworm, *Bombyx mori*, to reduce Folate and Sepiapterin

The mutant *lemon* of the silkworm is characteristically yellow in colour, accumulating a fluorescent pigment, xanthopterin-B_1, in the skin. Extract of the fat body of the wild-type silkworm converts this pigment into a non-fluorescent product[1]. There is some evidence to support the view that xanthopterin-B_1 is identical with sepiapterin[2], which is known to be reduced, in the presence of reduced nicotinamide dinucleotide phosphate (NADPH), by a folate reductase from chicken liver and *Drosophila*[3,4].

In the acetone-powdered fat body of the wild-type silkworm we noticed that the power to reduce folate was practically lost after six months cold-preservation while the activity to reduce sepiapterin remained unchanged, and we inferred that two different enzymes, folate reductase and sepiapterin reductase, were responsible for attacking the respective substrates. Further experiments with improved preparations also supported this inference.

To obtain sepiapterin reductase solution, the fat body was homogenized with 10 volumes of McIlvaine's buffer (*p*H 5·0) and twice centrifuged (12,000 and 40,000 r.p.m., 30 min each time); clear supernatant was used. Activity of this preparation was determined by measuring the decrease in optical density at 420 mμ ($-\Delta E_{420}$) per h (of incubation at 37° C) per mg protein, of the reaction mixture of sepiapterin[5] (crystallized from the fly mutant *sepia*, 0·02 μmole), NADPH (0·2 μmole), buffer (*p*H 5·0, 30 μmoles), and enzyme (0·1 ml.), brought to a total volume of 1·0 ml.

For the enzyme of folate, the fat body was extracted with 2 volumes of potassium phosphate buffer (0·1 M, *p*H 6·0), centrifuged (12,000 r.p.m., 30 min), filtered and dialysed against distilled water (about 15 h). A mixture of folate (0·136 μmole), NADPH (0·2 μmole), buffer (*p*H 5·0, 100 μmoles), and enzyme (0·5 ml.), brought to a total volume of 2·5 ml., was incubated for 1 h at 37° C and then heated for 3 min over boiling water; the amount of the resultant tetrahydrofolate (FAH_4) indicated the

enzyme activity, expressed in μg/h/mg protein[6]. Protein was determined by the method of Lowry *et al.*[7].

Both preparations from the wild-type independently rise and fall in activity during larval development after the fourth instar moulting (Fig. 1). Rapid and unrecovered loss of the folate-reducing activity can be seen in earlier pupal days when the activity of sepiapterin reductase, once much depressed, starts to rise again. Fig. 2 illustrates the results with similar preparations from the mutant *lemon*, which, as could be expected from the nature of accumulating xanthopterin-B_1, shows no activity of reducing sepiapterin during the whole period. Rise and fall of the folate-reducing activity in the mutant occurs rather like that in the wild-type. Chemical separation of these reductases is in progress.

This work was aided by a research grant from the Ministry of Education.

Microbial Degradation of Cephalosporin C

The antibiotic, cephalosporin *C*, is closely related to the penicillin family and displays the same mode of action[1].

Penicillin *N*

Cephalosporin *C*

R = D-α-aminoadipic acid

Although cephalosporin *C* possesses the β-lactam ring—the substrate site of penicillinase action—it is resistant to this enzyme and, in fact, acts as a competitive inhibitor. It is, however, attacked by a 'cephalosporinase' found in crude preparations of penicillinase from *Bacillus cereus*[2] and by a citrus acetyl esterase[3]. Although little is known about the site of attack by cephalosporinase, its action causes inactivation of the antibiotic with the loss of 260 mμ absorption and liberation of one acidic group. The esterase converts cephalosporin *C* to deacetylcephalosporin *C*, which retains the properties of ultra-violet absorption and resistance to penicillinase but which is a less-active antibiotic. We have now found that these two enzymatic activities are present in many bacteria and actinomycetes but not in the moulds examined.

About 200 freshly isolated marine micro-organisms (we thank T. Demny for providing these isolates and for classifying them into bacterial, actinomycete and fungal groups—they were all isolated from marine environments) were first screened for the ability to grow in the presence of 50 μg/ml. of crystalline cephalosporin *C* (provided by E. Inamine and T. Jacob) and to degrade the antibiotic. The method was similar to that used by Gots[4] to detect penicillinase producers. Each Petri plate, containing cephalosporin *C* and 0·1 per cent yeast extract in nutrient agar and seeded with *Escherichia coli* W, was inoculated with ten different isolates. Sixty-six of the 117 bacterial isolates, 36 of the 43 actinomycete cultures and 37 of the 41 fungi were resistant to the antibiotic and formed colonies at 28° C. The presence of satellite zones of *E. coli* around and under the colonies indicated degradation of cephalosporin *C* since the *E. coli* cells could not grow in the presence of 50 μg/ml. of the antibiotic. Table 1 shows that 70 per cent of the growing actinomycetes and 41 per cent of the bacteria degraded the antibiotics; the fungi lacked this ability.

Table 1. Degradation of Cephalosporin *C* by Marine Micro-organisms

Medium	Parameter	No. of isolates: Bacteria	Actinomycete	Fungi
Agar	Colony formation	66	36	37
	Cephalosporin *C* degradation	27	25	0
Liquid	Cephalosporin *C* degradation*	27	25	—
	Complete cephalosporin *C* destruction*	14	22	—
	Deacetylation of cephalosporin *C**	20	19	—

* Under one or more of the five experimental conditions described in the text.

Further study of the 52 cultures which were capable of degradation on agar was accomplished by exposure of cells to solutions of cephalosporin *C* under five different experimental conditions: (*a*) *Growing cells.* Cells were grown in Bacto Penassay broth containing 1 mg/ml. cephalosporin *C* for 1 day at 28° C on a shaking machine. (*b*) *Resting cells, pH* 7. Cells were incubated without shaking in 0·05 M phosphate buffer containing 4 mg/ml. cephalosporin *C* plus toluene at 28° C for 1 day. (*c*) *Resting cells, pH* 5·5. Same as (*b*) using 0·05 M citrate buffer. (*d*) *'Adapted' resting cells, pH* 7. Cells which were first grown for 1 day in the presence of 1 mg/ml. cephalosporin *C* were centrifuged and exposed to 4 mg/ml. cephalosporin *C* in 0·05 M phosphate buffer plus toluene for 4 h at 37° C with shaking. (*e*) *'Adapted' resting cells, pH* 5·5. Same as (*d*) using 0·05 M citrate buffer.

After the exposures, the incubation mixtures were centrifuged. The supernates (50 μl.) were chromatographed on Whatman No. 1 filter paper for 16 h in the descending direction. The solvent (isopropanol : pyridine : water; 65 : 5 : 30) was allowed to drip off the end of the sheet. Standards of cephalosporin *C* and deacetylcephalosporin *C* were also chromatographed. The antibiotic spots were detected by bioautography on large agar dishes seeded with *Bacillus subtilis*. Deacetylcephalosporin *C* migrated more slowly than cephalosporin *C* under the foregoing conditions.

Judging from the size of the cephalosporin *C* zone and the presence or absence of a deacetylcephalosporin *C* spot, we found that all 52 cultures attacked cephalosporin *C* under one or more of the incubation conditions. Three-quarters of the bacteria and actinomycetes tested showed esterase action (Table 1). Approximately half the bacterial isolates and almost all the actinomycetes were so active under one or more conditions that no cephalosporin *C* spot was detected. Quantitative bioassay of such supernatants by an agar-diffusion technique indicated more than 90 per cent destruction in these cases.

To complement the foregoing, 273 known bacterial species, selected at random from the stock culture collection, including almost all representative genera and/or species, were screened by the resting cell method (*b*). Also included were 25 different genera and/or species of yeasts. These cultures had no known previous contact with cephalosporin *C*. Of the bacterial cultures, 113 or 41 per cent, degraded cephalosporin *C* completely, whereas 16, or 7 per cent, formed the deacetylcephalosporin *C*, without further destruction of the molecule. Only one yeast was found to deacetylate the antibiotic, but none was capable of complete destruction.

Ninety-nine cultures of actinomycetes, freshly isolated from soil samples, were also tested directly in the resting

cell method (*b*) for a short incubation period of only 4 h. Within this period, 9 per cent of the actinomycetes completely destroyed the cephalosporin and another 10 per cent deacetylated the substrate.

Thus, bacteria and actinomycetes are potent producers of enzymes capable of destroying or deacetylating cephalosporin *C*. In no case, however, was a culture found which could remove the aminoadipic acid side chain from the molecule, thereby producing the cephalosporin nucleus—7-aminocephalosporanic acid.

PHYSIOLOGY

Evidence of the Mechanism of Ouabain Inhibition of Cation Activated Adenosine Triphosphatase

Ouabain has been shown to inhibit electrolyte transport in a number of tissues, including erythrocytes[1,2], brain and kidney[3,4]. Ouabain also inhibits that adenosine triphosphatase obtained from membrane and sub-cellular preparations which is stimulated by sodium plus potassium ions[5–7]. Recent work has shown that this enzyme must play an important part in the mechanism of active ion transport[7–10].

We have been able to demonstrate[11] that a heavy microsome sub-fraction of guinea pig kidney cortex sedimented at 40,000*g* from a tissue homogenate in 0·25 M sucrose and afterwards treated with deoxycholate by a procedure modified from Skou[8] contains in high yield a sodium plus potassium-activated adenosine triphosphatase reaction

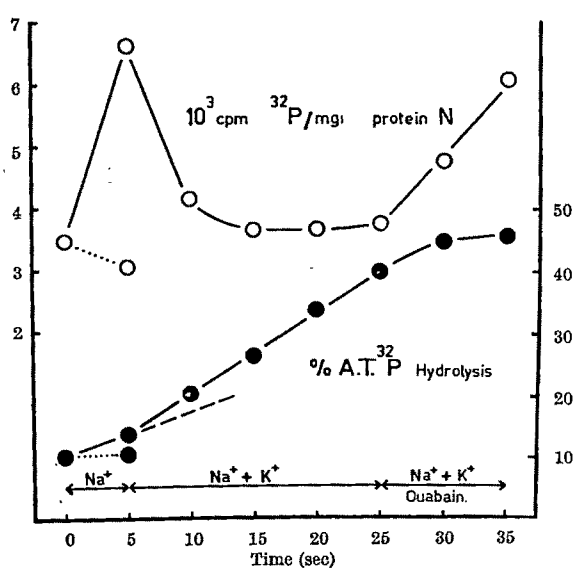

Fig. 1. Incorporation of phosphorus-32 from AT^{32}P into a microsomal adenosinetriphosphatase preparation incubated at 37° in a system to which the sequential addition of 80 mM sodium ions, 20 mM potassium ions and 0·1 mM ouabain was made. ATP + 2 mM K+ + 0·1 mM ouabain	87,000

* Incubated for 5 sec at 37° with carrier-free ^{22}Na at *p*H 7·6 in 0·05 M imidazole-glycylglycine buffer.

which is inhibited by ouabain and has other characteristics associated with active ion transport systems[6,7,12].

In experiments using this microsomal ATPase preparation and AT^{32}P as substrate we have been able to demonstrate the incorporation of phosphorus-32 into a phosphorylated compound which appears to be an intermediate in the overall hydrolysis of AT^{32}P to ADP and orthophosphate labelled with phosphorus-32 (ref. 13). Table 1 shows that the level of incorporation of labelled phosphorus into this microsomal material is greatly increased in the presence of sodium but not potassium ions, and is insensitive to ouabain. When both sodium and potassium ions are present together the hydrolysis of ATP is increased, but the level of phosphorus incorporation is reduced to near control values. On the other hand, addition of 0·1 mM ouabain to the sodium and potassium containing system results in inhibition of ATP hydrolysis and increased incorporation of phosphorus into the microsomal enzyme protein.

On the basis of these and other experiments in which sodium and potassium ions and ouabain were added in sequence to the incubation system (Fig. 1) we propose that the overall hydrolysis of ATP by this sodium plus potassium activated ATPase system proceeds by at least two stages. The first step is the formation of an intermediate compound which is dependent on the presence of sodium ions. The second step of the reaction is the subsequent phosphorolysis of this intermediate compound with the release of orthophosphate; this latter reaction is both dependent on potassium ions and is completely inhibited by low concentrations of ouabain.

The suggested mechanism is as follows (cf. ref. 13):

$$\text{Enzyme} + \text{AT}^{32}\text{P} \xrightarrow{x\text{Na}^+} [\text{E} \sim {}^{32}\text{P}]\text{Na}_x + \text{ADP} \qquad (1)$$

$$[\text{E} \sim {}^{32}\text{P}]\text{Na}_x \xrightarrow{y\text{K}^+} \text{E} + {}^{32}\text{P}_i + x\text{Na}^+ + y\text{K}^+ \qquad (2)$$

$$\text{Enzyme} + \text{AT}^{32}\text{P} \xrightarrow{x\text{Na}^+ + y\text{K}^+} \text{Enzyme} + \text{ADP} + {}^{32}\text{P}_i$$

Ouabain inhibits the hydrolysis of ATP by blocking the K+-dependent phosphorolysis and hence turnover of the intermediate complex (reaction 2).

In an examination of the sodium plus potassium activation of an 'intact' membrane ATPase system Whittam has reported an asymmetry of this system which orients the site of sodium activation internal to, and potassium activation external to, the cell surface[14]. Dunham and Glynn[5] have previously shown an antagonism between ouabain and K+ in this reaction, and these findings imply that the site of this antagonism is at a potassium-sensitive activation site, which is probably external to the cell surface, as also suggested by Post and Albright[15].

Preliminary experiments in which sodium-22 was incubated with this enzyme preparation have shown that there is an ATP dependent binding of sodium ions to this microsomal enzyme system, similar to that described by Järnefelt with brain microsomes[16].

The addition of K^+ to the incubation system resulted in a marked reduction in the binding of sodium-22. Ouabain did not reduce this initial sodium binding but at low concentrations could, in these experiments of only 5-sec duration, partially overcome the effect of potassium ions (Table 2). In other experiments of longer duration the effect of ouabain became more pronounced.

These findings also suggest that the action of ouabain is not on the formation of the phosphorylated complex, which is an intermediate in this reaction, or on the binding of sodium ions to it; but rather ouabain specifically inhibits the K^+-dependent phosphorolysis reaction which normally leads to the release of orthophosphate. In the presence of ouabain this intermediate tends to accumulate as its turnover is blocked.

The precise nature of the phosphorylated complex is as yet unknown, but total phospholipid extraction revealed 85 per cent of the total radioactivity (phosphorus-32) in a residual fraction containing all the original protein. This argues strongly against the complex being phospholipid in nature, for example, phosphatidic acid as suggested by Hokin and Hokin[17], and is in accord with the more recent findings of others[3,18–20].

Polystyrene Membranes for Covering Oxygen Electrodes for Use in Tissue

Bare electrodes for measuring tissue oxygen tension polarographically have several disadvantages. The electrode current depends not only on the oxygen tension at the cathode surface but also on the diffusion constant of oxygen and the blood flow pattern in the tissue in that region. In addition, the electrode current slowly falls when the bare cathode is exposed to tissue or blood. Clark[1] overcame this latter difficulty by using electrodes covered with a membrane for measurements in blood. The remaining difficulties in tissue can be overcome by using a membrane-covered electrode together with a pulsed voltage[2]. In this way the region around the cathode surface which is depleted of oxygen, due to the oxygen reduction process, is limited to the membrane and the thin saline layer behind it and does not extend into the tissue, where there is an unknown diffusion constant and blood flow pattern. The membrane-covered electrode, in contrast with the bare electrode, may be calibrated *in vitro* before use and the calibration will be valid for conditions *in vivo*. A number of membrane materials have been tried, for example collodion, rubber, polyethylene, polytetrafluoroethylene and 'Cellophane'. In the past we have found the most suitable membranes to be latex rubber sheaths. A disadvantage is that the electrodes must be mounted in the sheaths shortly before use, which can be a very lengthy operation. Furthermore, the rubber can move relative to the cathode and cause a change in calibration. Bartels *et al.*[3,4] reported that electrodes for use in blood samples can be covered with polystyrene and used with a continuously applied voltage. We have found that if our electrodes are coated with polystyrene and are used with a pulsed voltage, the more exacting requirements for measurements in tissue are met, and the disadvantages associated with rubber membranes are avoided. Such polystyrene-covered electrodes are independent of stirring effects outside the membrane, have a time response of a few seconds, are not poisoned by tissue and are easy to prepare. Further advantages are that there is no need for a membrane holder in the electrode assembly and the electrode tip can be made small and streamlined. Electrodes with an overall diameter of only 0·3 mm have been made and used satisfactorily in tissue.

The electrode system which we usually use has been described previously[5], and consists of 'Diamel'-coated gold wire 0·2 mm in diameter sealed with cold setting 'Araldite' into silver tubing of 0·3 mm internal diameter and 0·5 mm external diameter. The gold forms the cathode and the silver tube the anode of the electrode assembly. The external surface of the silver tubing is roughened on coarse emery paper to provide a key for the polystyrene. It is wiped clean and dipped into a 7 per cent w/w solution of polystyrene in trichlorethylene. The electrode is inverted and the membrane left to dry for 0·5 h under an electric light bulb. It is then soaked in physiological saline for at least a day before use in tissue. The electrodes are used in conjunction with the polarograph already described[6]. A 0·7-V pulse is applied for 0·5 sec every 10–20 sec. The current is sampled shortly before the end of each pulse.

If the electrode is tested in physiological saline immediately after the membrane has dried, no current flows between anode and cathode. If the end is left dipping in saline the system slowly becomes conducting. This may be accelerated by dipping the electrode for a few minutes in a mixture of 96 per cent ethanol in water saturated with sodium chloride, before it is left in the physiological saline. It appears that a layer of saline forms between the cathode surface and the inner surface of the membrane. Electrodes which have been coated by membranes which are too thin show a large increase in current when the medium outside is stirred. If the membrane is too thick either no current flows at all, or the current which does flow is not appreciably influenced by changes in oxygen tension in the outside medium. When the membrane is of the correct thickness its response to a change of oxygen tension in the outside medium is half complete in 2–5 sec and, when dipped in air-equilibrated saline, vigorous stirring does not increase the current by more than between 2 and 3 per cent. There is a linear relationship between oxygen tension and electrode current up to four atmospheres absolute. There is a background current in the absence of oxygen which is about a quarter of the total current obtained in air-equilibrated saline. This proportion is often greater when the membrane is too thick. The background current has a temperature coefficient of 1·5 per

cent per deg. C, whereas the oxygen reduction current shows no temperature dependence.

These electrodes have been successfully used in tissues over the past year.

Stereochemical Theory of Olfaction

In his recent article on this subject J. E. Amoore[1] ascribes the odours of substances to the size and shape of their molecules: the olfactory epithelium, he suggests, contains receptor sites of definite shapes and dimensions, and a substance with a molecule of configuration appropriate to fit into one of these sites will have one of the primary odours.

It is well known that some people are unable to detect the odours of certain substances: hydrogen cyanide is a case in point, many being unable to detect it. In fact, a few years ago, R. L. Kirk and N. S. Stenhouse[2] showed that ability to detect it was inherited, a sex-linked recessive gene being possibly involved. There are also other odours (such as vanilla, violets, etc.) which cannot be detected by everybody. In the case of hydrogen cyanide there is a further complication. Those who can detect it describe it as having an almond odour. The same kind of odour, though different in degree, is reported for benzaldehyde and nitrobenzene: however, people who are unable to detect hydrocyanic acid can, I believe, detect both the latter substances.

It would be of interest to hear how these phenomena can be fitted into Amoore's theory. In his article, he refers to the almond odour but not in the present connexion.

B. Fullman

46 Marlborough Place,
London, N.W.8.

[2] Kirk, R. L., and Stenhouse, N. S., *Nature*, **171**, 698 (1953).

Fullman (preceding communication) has raised the important question of how cases of partial anosmia can be fitted into my stereochemical theory of olfaction[1]. Unfortunately, the question cannot be answered as succinctly as it can be posed, because I have no single comprehensive answer. Each chemical example of partial anosmia will probably need special consideration.

I would anticipate that, by analogy with colour-blindness, certain individuals might be deficient in one type of receptor (or more), and hence lack the ability to perceive a whole class of primary odours. This kind of anosmia has been reported to appear artificially during recovery from vitamin A deficiency[2], and during recovery from accidental damage to the olfactory area by an alcoholic solution of gymnemic acid[3]. The majority of reported anosmias, however, involve not large classes of odours but circumscribed families of chemicals, or even single compounds, as pointed out by Fullman.

Where a family of chemicals cannot be perceived by a subject, it could be suggested that his receptor sites for the corresponding primary odour have an abnormal shape. For example, Guillot[4] found a number of individuals who normally could not perceive the macrocyclic musks, one subject who could not detect the steroid musks, and one who could perceive neither, but this last case was able to smell the nitro musks. Guillot explained this by postulating at least three fundamental odours for the musk sensation. However, Johnston and Sandoval[5] have shown that muskiness is a valid primary category, organoleptically and semantically. I would attempt to explain Guillot's observations by suggesting that his deficient subjects have musk receptor sites which are abnormally short (say 10·5 Å long instead of the normal 11·5 Å), while retaining the usual width of 9 Å. Such a site would exclude the longer steroid and macrocyclic musk molecules while still accepting the shorter, wider nitro musks. More detailed consideration of Guillot's observations will have to await refinement of my postulated dimensions for the normal musk site.

Most of the known subjects with partial anosmia have been tested on far too few compounds for it to be possible to map out the true extent of their anosmia. In the absence of evidence to the contrary, I suggest that such anosmias are to be explained as indicated here, by an abnormal configuration of the receptor site in the deficient individuals.

However, Fullman cites the example of hydrogen cyanide, which some persons are unable to smell, but those who can do so sometimes consider it to have an odour reminiscent of bitter almonds. It should be noted at the outset that Meyer, who made a special study of the odour of liquid HCN and its aqueous solution, reported that the smell of HCN is quite different from that of bitter almonds, with which he considered it was frequently incorrectly associated. He described its odour merely as penetrating and pungent[6]. Actually (assuming that the almond odour is not simply due to an impurity) hydrocyanic acid represents a yet more fundamental difficulty than those mentioned by Fullman, for I am rather at a loss to explain why it has an almond odour at all. Its molecule is very small, far too small to satisfy any of the three receptor sites (camphor, floral and pepperminty) which I postulated[7] go to make up the complex almond odour. In fact I conceded that hydrocyanic acid represents the only odorant example I encountered which really defied all reasonable explanation[8].

I am inclined to treat hydrocyanic acid as a special case for the time being, rather than distort the whole stereochemical theory to include one recalcitrant exception. It must be remembered that hydrocyanic acid possesses a number of special properties, very rarely found in a single compound. It is an exceptionally strongly associated liquid, very chemically reactive, and exceptionally poisonous. Any or all of these three unusual properties might conceivably account for its odour, as follows.

Hydrogen cyanide molecules, even in the vapour state at room temperature, have a remarkable tendency to associate by hydrogen bond polymerization into chains of indefinite length[9]. Lateral association of such chains by dipole attraction might also be anticipated. Perhaps in this way assemblages of hydrocyanic acid molecules build up to sufficient size to satisfy the three receptor sites to produce an almond odour. Alternatively, the chemical reactivity of hydrocyanic acid suggests the possibility that it might combine with some compound present in the nasal mucus or the olfactory epithelium, thereby converting it into a molecule which has an almond odour. Wright[10] noted that hydrocyanic acid does not fit into his (vibrational) odour theory either, and suggested that its odour is produced indirectly, on account of its chemical reactivity. Meyer[6] observed that hydrocyanic acid anæsthetizes the olfactory nerves in a few seconds, so that the odour soon cannot be perceived. Possibly the various primary odour receptors are anæsthetized at different rates. If the other four receptor types were extinguished before the camphor, floral and pepperminty types, then the residual resting discharge in these three would remain

for a while, and might give an impression of an almond odour.

The further complication in the smell of hydrocyanic acid is that those who cannot smell it are nevertheless able to detect the almond odour of benzaldehyde and nitrobenzene (see, for example, Guillot[11]). This means that their neural circuits for recognizing the complex odour of almond are intact, and that one must look elsewhere for an explanation of their deficiency. Small variations in the shapes of the receptor sites will not explain the phenomenon either, because three sites are involved, and multimolecular association has to be postulated in order to fill the receptor site at all. Individual variability in the susceptibility of different subjects' olfactory receptors to the anæsthetizing action of hydrocyanic acid would be a better explanation, in that their receptors might be anæsthetized before they could even detect an odour in the first place. This will explain the very variable assessments of the odour of hydrocyanic acid by different observers. Perhaps the best explanation is afforded by the hypothesis that hydrocyanic acid itself has only a pungent odour, but combines with some substance in the nose to produce an almond-smelling compound. This would be in accord with the evidence that inability to smell hydrocyanic acid is inherited along Mendelian lines[12]. Presumably the precursor of the almond-smelling adduct is absent from the nasal sinuses of the partially anosmic minority[10].

I have dealt in some detail with the paradox of hydrogen cyanide's odour, and some people's anosmia to it, because it represents the sole serious objection to my theory, so far as I am aware. My simple stereochemical theory cannot account for its almond odour without introducing special supplementary assumptions. I consider that the odour of this altogether exceptional molecule is brought about indirectly by one or other of the foregoing mechanisms, and I believe that in due course it will turn out to be 'the exception that proves the rule'.

A Metabolic Regulating Device based on the Actions of Human Growth Hormone and of Insulin, Singly and Together, on the Human Forearm

There have been several reports from the laboratories of F. G. Young (Ketterer, Randle and Young[1], Korner and Manchester[2], Korner[3]) suggesting that growth hormone directs the action of insulin on muscle 'away from carbohydrate toward protein synthesis'. Although some of the intimate detail of the proposed hypothesis concerning growth hormone action may be erroneous, the basic notion, as advanced by Korner[3], that, in the presence of growth hormone, some actions of insulin are preserved, whereas other effects are blunted, is very attractive. Placed in juxtaposition to observations from this laboratory on the effects of close intra-arterial injection of insulin and of human growth hormone, singly and together, on muscle and adipose tissue metabolism *in situ* in the forearm of man, it provides a clearer picture of the day-to-day role of human growth hormone and of insulin, and thus of their place in the economy of the normal adult.

We propose that, during a day, metabolism is dominated alternately by the action of insulin, or of human growth hormone, or of the combined effects of the two, in a three-phased cycle determined by the intake of food. Exposure to insulin in the 'immediate post-prandial period' encourages storage of carbohydrate and fat (phase I), exposure to human growth hormone plus insulin in the 'delayed post-prandial period' encourages protein synthesis (phase II) and exposure to human growth hormone in the 'remote post-absorptive period' encourages mobilization and peripheral oxidation of fat and retards translocation of glucose into muscle and adipose tissue (phase III).

The hypothesis was suggested by the following previously recorded observations:

(1) Yalow and Berson[4] and Glick, Roth, Yalow and Berson[5] have measured insulin and human growth hormone levels in blood in the basal state and following an oral glucose load. There is a 7- to 10-fold increase in plasma insulin concentration 30–60 min after a glucose meal and plasma human growth hormone falls, usually to zero. Plasma human growth hormone returns to basal values two to three hours after the glucose load, when plasma insulin concentration is still many times higher than its basal value. During the next few hours, plasma human growth hormone continues to rise, while insulin gradually returns to its basal concentration. If no food is taken and fasting persists for several days, insulin usually disappears from plasma[6] and human growth hormone concentration rises to levels reported in patients with acromegaly[5].

We can therefore consider three phases as man cycles between feast and famine (Fig. 1). In phase I, the immediate post-prandial period, peripheral tissues are exposed to insulin mainly. In phase II, the delayed post-prandial period, both insulin and human growth hormone circulate in high concentration. If the food-free interval is prolonged, human growth hormone concentration persists at a high level and insulin almost disappears (phase III, the remote post-absorptive period); that is, human growth hormone acts nearly alone.

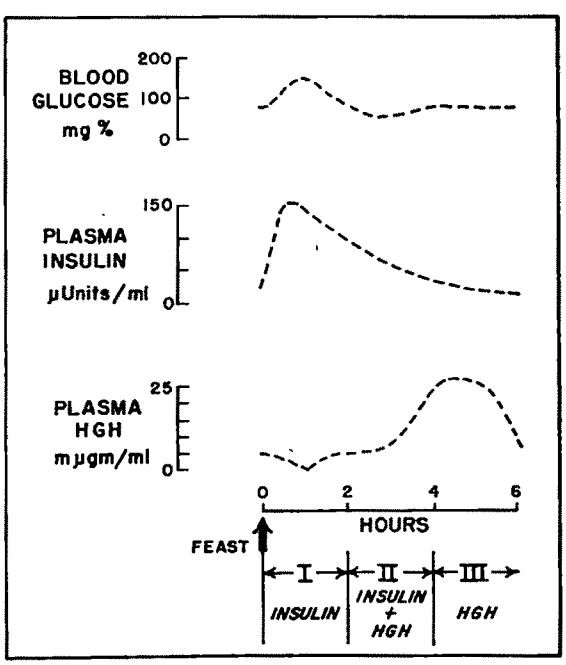

Fig. 1. Suggested variations in plasma insulin and human growth hormone concentrations during one feast–famine cycle. Curves are from Yalow and Berson (ref. 4) and Glick, Roth, Yalow and Berson (ref. 5)

(2) Close intra-arterial injection of insulin alone[7,8] in a concentration similar to that obtaining in the immediate post-prandial period produces the following effects on forearm metabolism in normal man: (*a*) a 10-fold increase in glucose uptake by muscle; (*b*) a 6-fold increase in uptake of glucose by adipose tissue; (*c*) obliteration of free fatty acid release from adipose tissue. The glucose taken up by peripheral tissues is stored rather than oxidized.

(3) Close intra-arterial injection of human growth hormone in normal subjects[9] produces the following: (*a*) enhanced release of free fatty acids from forearm adipose tissue; (*b*) enhanced uptake of free fatty acids by forearm muscle; decreased glucose uptake by forearm tissues.

(4) Present ideas on the interaction of insulin and human growth hormone may be summarized as follows. It has been shown in many species (the cat[10], the dog[11], the rat[12] and man[13]) that growth hormone will induce nitrogen retention only in the presence of 'adequate' amounts of insulin. This has given rise to the notion, reviewed recently by Korner[14], that growth hormone shuts off insulin's action on glucose uptake in order to let insulin exert its protein-anabolic effect. This is not quite our view. An alternative proposal will be made later. Whatever the mechanism, an insulin requirement for the protein-anabolic effects of human growth hormone is recognized. The missing link on which we have required information is: What effect does insulin exert on the fat-mobilizing properties of human growth hormone? To this end the following observations were made:

In six subjects with active acromegaly, the output of free fatty acids from adipose tissue (as reflected by negative arterio-superficial venous free fatty acid differences across the human forearm) was enhanced in the basal state, a finding which is consistent with endogenous over-production of human growth hormone. Close intra-arterial injection of insulin into the brachial artery in doses previously standardized in control subjects met with the anticipated poor response with respect to glucose movement into muscle (Fig. 2) and adipose tissue, but insulin-induced inhibition of free fatty acid release from forearm adipose tissue was at least normal (Fig. 3).

These observations were also true when insulin was administered in similar fashion to three normal men in whom endogenous human growth hormone production was stimulated by a 66-h fast[15], and we have reproduced

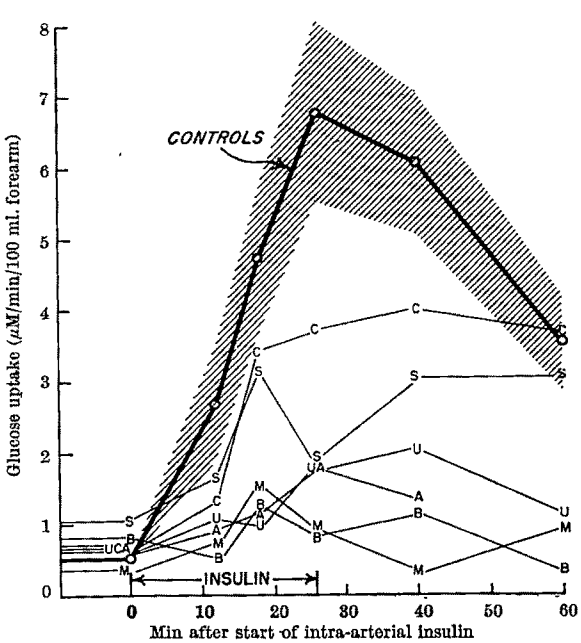

Fig. 2. Effect of insulin on forearm glucose uptake in acromegaly. Shaded area represents mean ± *S.E.* of mean among ten normal subjects (ref. 7). Individual lines indicate glucose uptake in acromegalic subjects, identified by initials

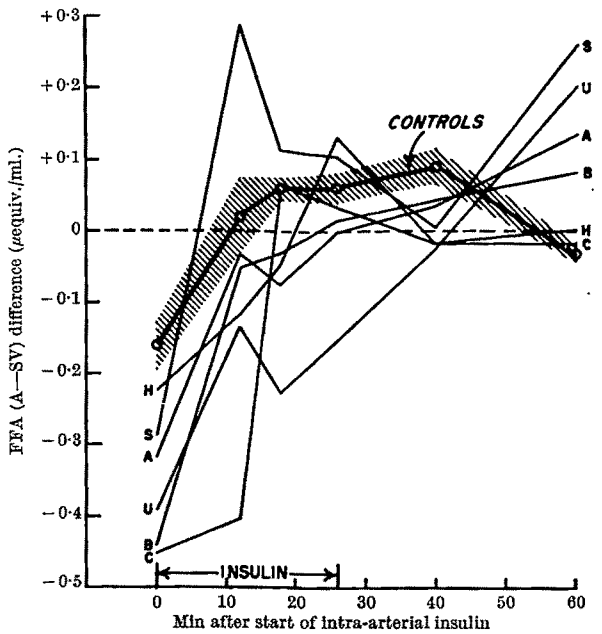

Fig. 3. Effect of insulin on arterio-superficial venous free fatty acid differences in acromegaly. Shaded area represents mean ± *S.E.* of mean among five normal subjects (ref. 8). Individual lines indicate arterio-superficial venous free fatty acid differences before, during and after insulin in acromegalic subjects, identified by initials

the same effect in five normal subjects by intra-arterial infusion of human growth hormone (0·2 μg/kg min) and insulin (100 μU/kg min) simultaneously. In them, there was but little response with respect to glucose uptake by forearm, suggesting that human growth hormone had inhibited insulin action, but there was total inhibition of release of free fatty acid, suggesting that insulin had exerted its full effect. It is therefore incorrect to speak of human growth hormone as inhibiting insulin. It is probably preferable to consider that the two hormones interact to behave like a new hormone that does not stimulate glucose uptake by muscle or adipose tissue but does reduce or obliterate release of free fatty acid from adipose tissue and, we suggest, also stimulates protein synthesis.

We are led to the following synthesis: in the first hour or two of 'feast' (phase I), insulin, acting alone, encourages storage of carbohydrate and fat; after the second hour (phase II), human growth hormone is released but acts solely as an anabolic agent, the levels of endogenous insulin inhibiting its fat-mobilizing action and catalysing its protein-anabolic effects. In the remote post-absorptive period of 'famine' (phase III), human growth hormone acts exclusively as a fat-mobilizing agent since the circulating plasma insulin-level is below that which can either inhibit release of free fatty acid or stimulate the anabolic action of human growth hormone. These notions would resolve the apparent paradox of attributing to human growth hormone a central role in metabolic adaptation to starvation[16], which can be looked on as an exaggeration and perpetuation of the post-absorptive state.

We are therefore suggesting that whether human growth hormone is predominantly protein-anabolic or lipid-catabolic may be a function of the plasma insulin concentration, which, in turn, depends on whether or not the animal has recently eaten. The consequence is that carbohydrate, fat and protein storage is promoted during the post-prandial period, and lipid catabolism and oxidation and glucose preservation is made easy during the post-absorptive period, so that the supply of substrates is smoothed out over the day.

Photodynamic Effect of Diidroquinidine on Isolated Hearts of Mammals

THE photodynamic action of diidroquinidine chloridrate on *Paramecia*, blood serum and isolated heart of a frog has been observed by Pace *et al.*[1]. Examination of this particular action of diidroquinidine on the isolated heart and the effect of some photodynamic substances (that is, hæmatoporphyrin) on the function of isolated hearts of mammals and amphibians[2,3] suggested the opportunity of investigating the photodynamic effect of diidroquinidine on isolated mammal hearts by electrocardiographic technique.

Hearts from 10 guinea pigs and 10 rabbits were used. The animals were anæsthetized by an intraperitoneal injection of ethylic urethan, 25 per cent, and the hearts isolated by the usual Langendorff technique. Aorta was incannulated and hearts were washed and perfused with a Ringer solution at 37° C and constant oxygen tension. Two platinum electrodes were applied to the right atrium and left ventricle and the ECG was recorded in lead I by an ink electrocardiograph. The mV was 0·5 cm. The diidroquinidine solution was 10^{-4} M in the experiments carried out on the guinea pig hearts and 10^{-3} M in those on the rabbit hearts. Light was supplied by a low-pressure mercury lamp at 6×10^3 ergs/cm²/sec, 50 cm from the heart and filtered through 5 mm of glass so that $\lambda > 320$ mμ.

The diidroquinidine solutions at 37° C were injected into the Ringer perfusion pipe. After 2 min for rhythm stabilization and regularization a first record in the dark and under irradiation showed no modification of the ECG. The diidroquinidine solution was then placed in the dark.

After 2 min the first ECG modifications were recorded. In the guinea pig heart a slowing down of the rhythm could be observed (Fig. 2) followed by a period of tachycardia with elevation of the ST segment. In some cases these modifications shared a monophasic wave pattern. At this stage the records in the dark showed a reduction in the voltage of the ventricular complexes. A further perfusion with diidroquinidine and irradiation determined bradycardia after about a 2 min period; the monophasic wave disappeared and ST returned to the base line with normalized *T* wave. Further perfusions with diidroquinidine in the dark confirmed the bioelectric phenomenon described in the first part of the experiment. Using rabbit hearts (perfusion with diidroquinidine in the dark), a remarkable prolongation of *QRS* with the pattern of a bundle branch block was noted. The same alterations described with the guinea pig hearts could be recorded.

In one case (Fig. 1), we recorded a complete auriculoventricular block 2 : 1, which disappeared after diidroquinidine perfusion and irradiation and reappeared as a complete auricoventricular block after cutting down the irradiation: only the *P* waves could be recorded. At this point the irradiation determined the immediate appearance of abnormal but rhythmical *QRS* complexes that showed a revival of the heart function. After about

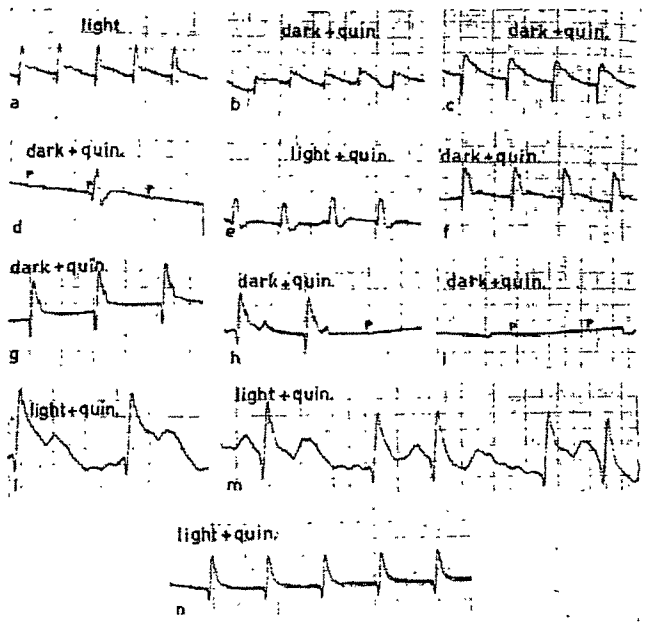

Fig. 1

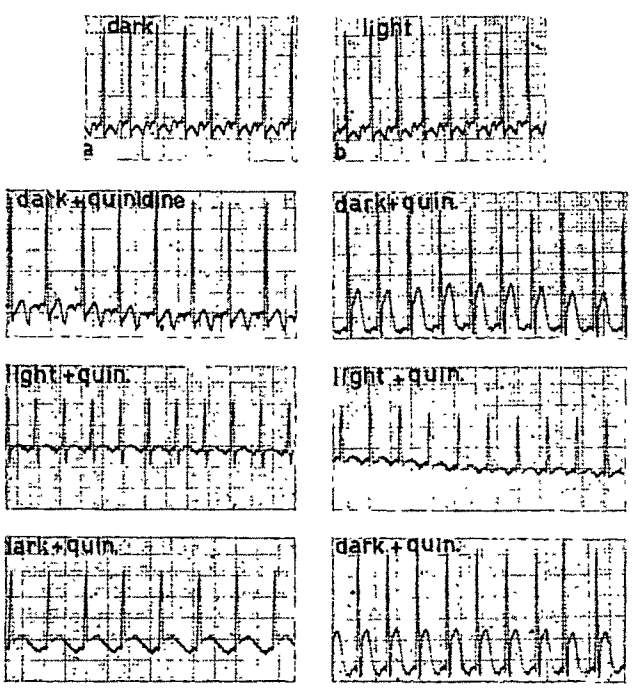

Fig. 2

2 min the rhythm became regular and the records showed the normal (original) pattern.

The modifications induced on the ECG by diidroquinidine chloridrate solutions in the dark can be identified with the well-known effect of this substance on the specific conduction tissue and on the muscles of the heart, that is, a slowing down in the frequency and conduction of the stimulus as far as a partial and complete auricoventricular block, and toxic damage—probably on metabolic grounds. The latter alterations can be observed on the ECG on account of the modifications of ST and of the *T* wave. A monophasic lesion wave can be noted in some cases.

Examination of our records during irradiation and diidroquinidine perfusion shows in all cases the electrical modifications to be interpreted as an improvement of the heart functions. Indeed, the normalization of ST, of the *T* wave and of the ventricular complexes and chiefly the disappearance of the auricoventricular blocks, indicate that the normal action of the diidroquinidine was modified by light so that the substance has, in this case, a photosensitizing function.

This experiment is in accordance with our previous work on diidroquinidine as a photodynamic substance. The importance of the concentration of the substance to the photodynamic action must be pointed out, as while concentrated solutions induce a total and not reversible damage, more diluted solutions improve and regularize the functioning of the heart.

PHARMACOLOGY

Antitussive Activity of a New Local Anæsthetic Compound : Benzobutamine

Investigations of the relationships between the antitussive activity and other pharmacological properties of many known drugs[1] led us to conclude that local anæsthetic effect was very important in order to predict the antitussive activity of new compounds, especially if this action is accompanied by other pharmacological effects such as the antispasmodic and antihistaminic ones. A systematic investigation was then carried out on new synthetic derivatives possessing local anæsthetic properties in different degrees. The compound *N*(2-benzoyloxymethyl-2-phenylbutyl)-*N*,*N* dimethylamine (benzobutamine)[2] was found to have the most interesting antitussive activity among a series of many other related compounds. Benzobutamine displays local anæsthetic properties and, at the same time, shows antispasmodic, anticonvulsant and antihistaminic effects. In this communication a description of the pharmacological properties of this drug is given.

The local anæsthetic activity of benzobutamine was investigated in rabbits by instilling three drops (0·1 ml.) of an aqueous solution in the conjunctival sac, and observing the disappearance of the corneal reflex elicited by touching the corneal surface with a nylon thread. A comparative examination demonstrated that benzobutamine is as active as lidocaine.

The antispasmodic activity of benzobutamine, studied on the isolated rat gut in Tyrode at 37° C, was found to be the same as that of 'Trasentine®': the concentration effective in reducing 50 per cent of the effect of standard doses of barium chloride is 1·5 μg/ml. for both substances. In a little higher concentration (2 μg/ml.) benzobutamine inhibits also and in the same degree (50 per cent) the effect of histamine on isolated guinea pig ileum. Inhibition of the action of acetylcholine on the isolated rat ileum was produced only by higher concentrations of the product, that is, 5 μg/ml.

Although benzobutamine, given in toxic doses, produces clonic and tonic convulsions, it prevents the tonic phase of maximum electro-shock seizures in 50 per cent of mice when given in doses of 40 mg/kg intraperitoneally. Mice are also completely protected from pentamethylenetetrazol (120 mg/kg intraperitoneally) induced convulsions and death by 80 mg/kg of benzobutamine given 30 min before.

When injected subcutaneously in the rat in doses of 20 mg/kg, benzobutamine produces a slight analgesic effect, as determined according to Randall and Selitto[3].

The antitussive activity (Table 1) was tested in guinea pigs in which the cough was induced by inhalation of acrolein according to the previously described method[1]. The reduction of 50 per cent of the cough was obtained by 3·5 mg/kg subcutaneous injection of benzobutamine. Under the same experimental conditions the isodynamic doses of codeine, benzononatine, dextromethorphan and narcotine were found to be 4 mg/kg, 3 mg/kg, 6 mg/kg and 3·5 mg/kg respectively[1].

Table 1. Antitussive Activity and Acute Toxicity of Benzobutamine and Other Antitussive Agents

Products	Cough inhibition ED_{50} (mg/kg)				LD_{50} (mg/kg s.c.)
	a	*b*	*c*	*d*	
Codeine	4 s.c.	1 s.c. 7 orally	1·5 i.v.	4 s.c.	300 (ref. 7)
Dextro-methorphan	6 s.c.	—	2 i.v.	1–2 s.c. (ref. 5)	275 (ref. 8)
Benzononatine	3 s.c.	> 2 s.c.	1·5 i.v.	> 4 s.c.	230 (ref. 9)
Narcotine	3·5 s.c.	2 s.c.	> 20 i.v.	> 8 s.c.	390 (ref. 10)
Benzobutamine	3·5 s.c.	1 s.c. 5 orally	0·5–1 i.v.	> 8 s.c.	> 1,000

a, Acrolein inhalation in guinea pigs; *b*, aerosol of sulphuric acid in dogs; *c*, electrical stimulation of the superior laryngeal nerve in cats; *d*, electrical stimulation of sub-mucous tracheal tissues in dogs.

In dogs the cough induced by an aerosol of sulphuric acid (0·5 N) according to Winter and Flataker[4] was significantly reduced (56 per cent) by benzobutamine at 1 mg/kg subcutaneously and at 5 mg/kg orally. Codeine, at doses of 1 mg/kg subcutaneously and 7 mg/kg orally, produced the same degree of cough inhibition. Narcotine gave the same results in doses of 2 mg/kg subcutaneously, while benzononatine was found to be ineffective at doses of 2 mg/kg subcutaneously.

Benzobutamine was found to be inactive on the cough induced by electrical stimulation of sub-mucous tracheal tissues by means of chronically implanted electrodes, as described by Stefko and Benson[5], in doses up to 8 mg/kg subcutaneously. In the same test, benzononatine and narcotine were also found to be devoid of any inhibitory effect. Only codeine, morphine and dextromethorphan appeared to be active in reducing this experimental cough.

On the cough response, elicited by electrical stimulation of the superior laringeal nerve in anæsthetized cat according to Domenjoz[6], benzobutamine produced an inhibitory effect in doses of 0·5–1 mg/kg intravenously. The duration of this effect after the latter dose was of about 20 min. The isodynamic doses of other known antitussive compounds were found to be 1·5 mg/kg for codeine, 2 mg/kg for dextromethorphan and 1·5 mg/kg for benzononatine. Narcotine appeared completely ineffective also in doses of 20 mg/kg.

In rabbits and dogs benzononatine moderately depresses respiration only when given intravenously in doses of 2–5 mg/kg. Table 2 compares the effects of benzobutamine and codeine on the rate of respiration of rats (5 per group) previously treated with phenobarbitone (120 mg/kg intraperitoneally).

The results indicate that benzobutamine produces insignificant respiratory depression in doses of 10 mg/kg subcutaneously, while codeine, already at 5 mg/kg subcutaneously, is able to decrease the rate of respiration.

Table 2. Effects of Codeine and Benzobutamine on the Respiratory-Rate (per min) of Rats given Phenobarbitone (120 mg/kg i.p.)

Time (min)	0	10	20	30	40	50	60	80	100	120	140	160	180
Controls	120	126	108	116	116	132	120	168	144	140	124	132	130
Codeine:													
10 mg/kg s.c.	126	112	74	66	45	64	42	42	34	20	62	38	64
5 mg/kg s.c.	120	98	94	101	86	86	94	88	106	98	114	162	166
Benzobutamine:													
10 mg/kg s.c.	122	130	116	108	110	116	138	110	120	116	166	116	133

Each figure is the average of data obtained from five animals. Lines under figures indicate a significant difference ($P \leq 0.05$) from controls.

The acute toxicity of benzobutamine was determined in *CF*-1 mice, and compared with that of other antitussive agents (Table 1). Long-term toxicity examinations were carried out in rats and dogs. No pathological signs were found at the end of a six months' treatment with oral doses of 25 mg/kg and 50 mg/kg in rats, and 30 mg/kg and 60 mg/kg in dogs.

Extensive clinical investigations, carried out according to a double blind schedule, have confirmed the good antitussive activity of benzobutamine in men and the absence of any side-effect[11].

The results obtained with benzobutamine confirm the previously mentioned hypothesis[1] of a relationship between the antitussive activity and other pharmacological properties.

The two most important properties of benzobutamine—local anæsthetic and spasmolytic—may be considered both as peripheral ones, and one could suggest that its mechanism of action resembles that suggested by Bein and Bucher[9] for benzononatine, which is practically the only antitussive agent the local anæsthetic properties of which are particularly marked. According to these AA. benzononatine acts through an anæsthesia of pulmonary receptors which are reached by the drug because of its peculiar tropism. However, other local anæsthetic agents proved to be effective in experimental cough[1], and, moreover, benzobutamine possesses probably a certain degree of activity on the central nervous system as suggested by its anticonvulsant action.

The demonstration of the activity of benzobutamine in man indicates that among the methods of screening for antitussive compounds the inhibition of cough, experimentally induced by inhalation of irritating agents, is to be considered as the most suitable one in order to predict a therapeutic effectiveness.

Potentiation of the Anti-reserpine Effects of Dihydroxyphenylalanine by Antidepressants and Stimulants

Dihydroxyphenylalanine (DOPA), the biological precursor of the catecholamines[1], causes stimulation of the central nervous system in normal mice[2] and mice treated with reserpine[3]. In the latter the effects of DOPA are dramatic; the mice are aroused from the reserpine-induced depression and become normal or hyperactive in behaviour[3]. Such arousal is thought to be effected through repletion of the reserpine-depleted catecholamines[3].

Inhibitors of monoamine oxidase (MAO) will enhance the repletion of amines by DOPA and will potentiate its central stimulatory effects in normal and reserpinized animals[3]. This potentiation probably depends on a sparing of the substrates of MAO. Other antidepressants, for example, imipramine ('Tofranil®', *N*-(γ-dimethylaminopropyl)iminbibenzyl hydrochloride) and amitriptyline ('Elavil®', 5-(3-dimethylaminopropylidene)-dibenzo [*a.d*] [1,4] *cyclo*-heptadiene hydrochloride), of proved clinical utility are not inhibitors of MAO. The latter compounds had the characteristics of tranquillizers when initially evaluated in experimental animals[4]. It has, however, been shown that imipramine has anti-reserpine activity[4–6]. It has also been demonstrated that imipramine enhances the ability of methamphetamine to increase the rate of rewarding self-stimulation in rats[7], and the facilitating activity of *d*-amphetamine on conditioned avoidance behaviour[6]. It has been suggested that the antidepressant effect of imipramine is the result of sensitization of central adrenergic receptors[4]. We have found that, like the inhibitors of MAO, the non-MAO-inhibiting antidepressants can potentiate the arousing effect of DOPA in reserpinized mice. In addition, the psychomotor stimulant *d*-amphetamine was found to have this activity in doses which cause no overt stimulation.

Female albino mice weighing 18–24 g were used in these experiments. Mice were reserpinized by the intraperitoneal administration of 10 mg/kg of reserpine (dissolved in acetic acid and diluted to the proper concentration with deionized water). Three hours after reserpine, at which time the animals were immobile with complete eye closure, *dl*-DOPA, in graded doses, was injected intraperitoneally and the mice observed for arousal. The criteria for arousal were induction of hyperactive behaviour and reversal of the eyelid closure. The percentage of animals responding at each dose was recorded, and a dose-effect curve constructed. Eight animals were used at each dose. The ED_{50} for DOPA-induced arousal is 1,080 mg/kg (19/20 confidence limits 963–1,264 mg/kg)[9]. The DOPA-potentiating potencies of the test drugs were evaluated as follows. The test drug was administered intraperitoneally in graded doses 2 h after 10 mg/kg of reserpine. One hour later the ED_5 (520 mg/kg) of DOPA, obtained by extrapolation from the dose-effect curve, was injected intraperitoneally. The incidence of arousal was recorded for each dose of the test drug. Dose-effect curves were constructed, and the dose of the test drug (ED_{50}) which caused 50 per cent of the animals to respond to the ED_5 of DOPA was estimated[9]. Neither the ED_5 of DOPA nor any of the doses of the test drugs used caused an arousal response alone. The drugs tested were nialamide ('Niamid ®'), imipramine ('Tofranil ®'), amitriptyline ('Elavil ®') and *d*-amphetamine sulphate. The arousal induced by the combination of the low dose of DOPA and the test drug was grossly identical to that caused by the higher doses of DOPA alone.

Table 1. ED_{50}'s for Potentiating the Arousal of Reserpinized Mice by DOPA

Drug	ED_{50} (mg/kg intraperitoneal)	19/20 Confidence limits
Nialamide	2·3	1·4–3·9
Amitriptyline	3·7	2·4–5·6
Imipramine	5·0	3·7–7·5
d-Amphetamine	0·55	0·33–0·93

Table 1 shows the ED_{50} values with 19/20 confidence limits for the drugs tested to potentiate the arousal of reserpinized mice by DOPA. The psychomotor stimulant *d*-amphetamine is more potent than the antidepressants.

In the case of the MAO inhibitor, nialamide, the effect is likely to be due to its anti-MAO activity and the consequent maintenance of high levels of the substrates of MAO, especially dopamine[3]. The results with imipramine and

amitriptyline reinforce the idea that many of the activities of the MAO inhibitors are possessed by substances which do not inhibit the enzyme. It is not established from our results that a similar mechanism of action is involved in the potentiation of DOPA by psychomotor stimulants and antidepressants. Since special tests[5–8] have shown that imipramine stimulates the central nervous system, it might be that the antidepressants, which do not inhibit MAO and the non-stimulating doses of psychomotor stimulants, exert their effect through a sub-threshold excitation (sensitization) of the central structures involved in the response.

We thank the Geigy Pharmaceuticals Co. for supplying the imipramine, the Merck, Sharp and Dohme Laboratories for supplying the amitriptyline and the Pfizer Laboratories for the nialamide.

HÆMATOLOGY

Hæmoglobins of Two Elephant Shrews

The Macroscelididae, elephant shrews of the order Insectivora, have been considered close relatives of some animals often classified as Primates—the Tupaiidae. Certain authors consider that the tupaiids and macroscelidids are very closely related[1]. It is generally conceded to-day that the Tupaiidae—the tree shrews of Malaysia—are Primates and that the Macroscelididae are not[2]. A recent author, nevertheless, still refers the tupaiids to the order Insectivora[3]. However the Tupaiidae are classified, it is clear that the Macroscelididae are Insectivora and that they may well represent a link between the two orders.

Our laboratory has been investigating the evolution of the hæmoglobin molecule among the Primates. We recently received an opportunity to study the hæmoglobin of two East African elephant shrews, *Petrodromus sultani* and *Rhynchocyon chrysopygus*, species of Macroscelididae. Blood was obtained by heart puncture of tranquillized shrews; syringes rinsed with heparin were used. The cells and plasma were separated by centrifugation and hæmolysates prepared in the usual fashion. Electrophoresis of hæmolysates was carried out in vertical starch-gels as described previously[4]. Hæmolysates were dialysed against the same buffer as that used for the gels, 0·027 M *tris*(hydroxymethyl)aminomethane plus 0·020 M boric acid, *p*H 8·6. Tests for alkali-resistant pigments were carried out according to the method of Singer *et al.*[5].

A typical gel is illustrated in Fig. 1. Two bands appear in each of the samples from *Rhynchocyon*. The slower band moved somewhat farther than human hæmoglobin A. Samples of human A, S, and cord blood (F plus A) were run on the gel for comparison. The samples of *Petrodromus* are, in all cases, quite smeared. Examination of the gels with transmitted light showed that two bands appear to be present, both of which have mobilities markedly less than the mobility of human hæmoglobin A. However, in one *Petrodromus* sample (Fig. 1, sample No. 9) in which two bands are also evident, they do not have the same mobility as the two bands found in the other samples. Four samples from *Rhynchocyon* and 12 from *Petrodromus* were tested.

The alkali denaturation test on the samples from *Rhynchocyon* demonstrated a relatively large proportion of alkali-resistant pigment. The mean value for the four samples was 51·9 per cent, and the range was 47·7–54·0 per cent. We had extremely small samples from *Petrodromus* and only three of these were large enough for the alkali denaturation test. The mean value of these three was 5·2 per cent, the range being 5·0–5·6 per cent.

The amount of alkali-resistant pigment in *Rhynchocyon* and the presence of two distinct components after electrophoresis suggest that one of the two bands is the alkali-resistant pigment. There is no similar obvious relationship between the amount of alkali-resistant pigment in *Petrodromus* and the pattern after electrophoresis. All the animals tested were adults, therefore it is clear that these are not fœtal pigments, even should their structural properties prove to be similar to human hæmoglobin F.

The proportion of alkali-resistant pigments found in *Rhynchocyon* is higher than that found in *Galago*, for example, and is similar to the proportions found in *Nycticebus* and certain Lemuridæ[4,6]. A single hæmoglobin sample from *Tupaia glis*, a tree shrew from Malaya, captured near Kuala Lumpur, was examined in our laboratory. The proportion of alkali-resistant pigment was 9·1 per cent[6]. Electrophoresis of the sample showed a single band moving somewhat more slowly than human hæmoglobin A (ref. 7). The difference in proportions of alkali-resistant pigments between *Rhynchocyon* and prosimian Primates is less than the variation among the prosimians themselves. It is the structure and possible special functions of these alkali-resistant pigments that require elucidation. Conclusions with regard to specific problems in taxonomy are still premature.

This work was supported by grant *RG* 6053 of the U.S. Public Health Service and was carried out during the tenure of a National Science Foundation senior post-doctoral fellowship held by one of us (J. B.-J.). The facilities of the Wellcome Trust Laboratory at the Medical Research Laboratory, Nairobi, Kenya, were generously

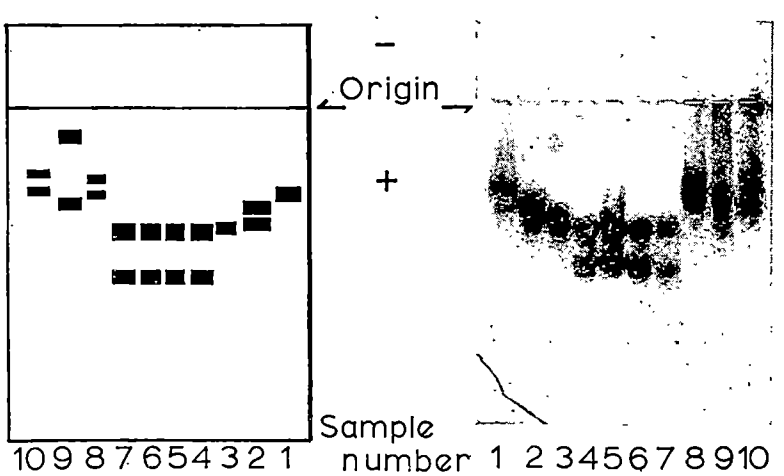

Fig. 1. Diagram (left) and photograph (right) of electrophoretogram of samples from *Rhynchocyon chrysopygus* (Nos. 4, 5, 6 and 7), *Petrodromus sultani* (Nos. 8, 9 and 10), and human hæmoglobins A (No. 3), S (No. 1), and A plus F (No. 2). The diagram was drawn from half the gel after it was stained with amido black. The photograph was made from the half the same gel after it was stained with benzidine. We find that better photographs, with greater contrast, are obtained from the benzidine-stained gels

made available by Dr. H. Foy and Dr. A. Linsell. We thank Mr. R. Clift and Mr. R. Caldecott for their assistance.

Sedimentation Characteristics of the Human Hæmoglobins A, F and E

IT is now well established that normal human hæmoglobin A consists of four polypeptide chains of two types named α and β (ref. 1). The normal fœtal hæmoglobin F also consist of four polypeptide chains of two types, namely, α and γ (ref. 2). Thus the difference between the Hb-A and Hb-F is the substitution of two complete γ-chains for the two β-chains. A number of physical and chemical differences between these two hæmoglobins have been discovered[3] which are undoubtedly associated with this replacement. However, no systematic study of difference, if any, in the sedimentation character of these two hæmoglobins appears to have been made as most of the previous sedimentation studies were concerned with Hb-A[4–8]. This communication describes comparative investigations of the sedimentation behaviour of two normal human hæmoglobins A and F. When the measurements were in progress, samples of pure hæmoglobin E were available from the blood of a homozygous subject (E. E.), whose blood contained 98 per cent Hb-E and 2 per cent Hb-F. Some sedimentation studies were also carried out with this abnormal human hæmoglobin E, which differs from hæmoglobin A by the replacement of a single amino-acid, glutamic acid, by lysine in the 26th residue of the β-chain[9]. No previous sedimentation examination of Hb-E has been carried out.

Hb-A and Hb-F samples were obtained from the blood of normal adults and from that of the cord of new-born babies. The Hb-F content of the different cord bloods, as determined by the method of Singer *et al.*[10], varied from 70 to 80 per cent. In all cases, red cells from the oxalated blood were collected by centrifugation and freed from the serum by repeated washing with isotonic saline. The serum-free red blood cells were hæmolysed with double distilled water and the hæmolysates were freed from the stroma by centrifugation at 3,000 r.p.m. for 30 min.

The concentrations of the hæmoglobin solutions were determined from the measured extinction at 540 mμ with a Zeiss spectrophotometer using $E^{1\%}_{1cm} = 8{\cdot}55$[11]. Rossi-Fanelli[7] showed both from light scattering and sedimentation experiments that the hæmoglobin molecules are easily dissociated. The degree of dissociation increases with increasing salt concentration from 0·1 M to 2·0 M sodium chloride and from 0·1 M to 0·5 M phosphate buffer. Hence, in the present series, all ultracentrifugal experiments were carried out in double distilled water at *p*H 6·8 with a Spinco analytical ultracentrifuge equipped with the schlieren optics and the standard 12 mm cell. The light source used was a General Electric *AH* 6 lamp and Kodak photomechanical films were used for recording the optical patterns.

The schlieren pattern (Fig. 1) in all experiments, characterized by the presence of one coloured symmetrical component, was found to travel as a single peak and no evidence of dissociation was found even at a concentration of 4×10^{-2} g/100 ml. Fig. 2 is a plot of sedimentation coefficient against concentration for Hb-E obtained in the present investigation. For comparison, the results of previous workers for Hb-A are also plotted on the same graph. One measurement on Hb-A carried out in the present experiments is also shown which agrees very well with previous measurements.

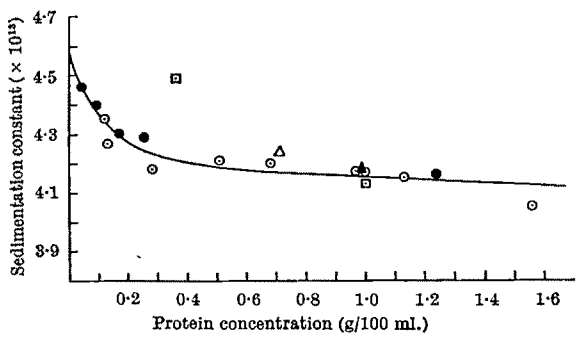

Fig. 2. Concentration dependence of sedimentation coefficient of hæmoglobins A and E. ●, Hb-E; ▲, Hb-A (present work); ⊡, Hb-A (ref. 8); ⊙, Hb-A (ref. 4); △, Hb-A (ref. 5)

It will be found that the sedimentation constants of Hb-E measured in the experiments described here as well as those of Hb-A obtained by previous workers fall on the same smooth curve. For concentrations above 0·3 g/100 ml., the results may be represented by a linear variation of S with C. However, for concentrations below 0·3 g/100 ml., the measured points deviate considerably from linearity and there is rapid increase of S with C. In fact, the present results fit better with two measurements of Kegeles and Gutter[4] at low concentrations than with the linear presentation given by them. The extrapolated value of $S^0_{20,w}$ for Hb-E (or Hb-A) was found to be 4·56. If this value of $S^0_{20,w}$ is combined with the diffusion constant of $6{\cdot}9 \times 10^{-7}$ for hæmoglobin A (ref. 4), one obtains a value of 64,150 for the molecular weight. The amino-acid compositions of the α- and the β-chains of Hb-A are now well established[12,13]. From these chemical studies the molecular weight comes out to be 64,450 in excellent agreement with that obtained from ultracentrifugal studies.

For a molecule with molecular weight 64,000, which is spherical and behaves in solution as ideal compact spheres, with smooth surface and which is not hydrated in solution, the sedimentation constant should have been 5·4 S. The discrepancy between the theoretical value of 5·4 S and the observed ones of 4·56 S (Hb-E and Hb-A) must be ascribed to the facts: (1) that the molecules are highly solvated while sedimenting, thus increasing the hydrodynamic volume and the frictional force; (2) that they do not behave as ideal, compact, hydrodynamic spheres. X-ray diffraction on hæmoglobin show clearly the presence of holes in the molecules and of folds and

Fig. 1. Schlieren pattern of hæmoglobin E, concentration 1 per cent at 56,100 r.p.m., recorded 40, 50 and 60 min after start

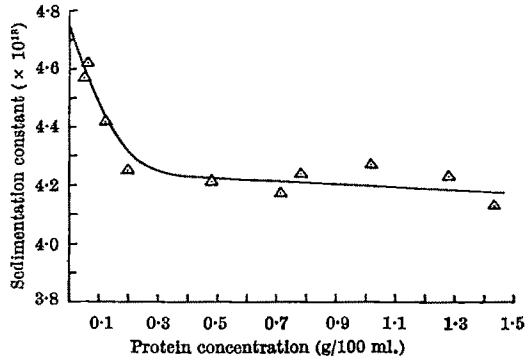

Fig. 3. Concentration dependence of sedimentation coefficient of hæmoglobin F

depressions on its surface where the different chains meet[14]. It is obvious that the hydrodynamic behaviour of such a particle will deviate considerably from that of the ideal compact sphere.

Fig. 3 shows the concentration dependence of S-values for Hb-F. The points are somewhat more scattered than in the previous case due to the fact that the measurements were made on hæmoglobin samples from the cord blood of six infants, where the per cent of Hb-A varied from subject to subject. The measurements on Hb-E, however, were all made with the blood from the same person. Again the results show that for $C > 0{\cdot}3$ g/100 ml. S varies almost linearly with C, while for $C < 0{\cdot}3$ g/100 ml. S increases more rapidly. The extrapolated value for $S^0_{20,w}$ for Hb-F was 4·74 S, slightly greater than what was found for Hb-E (or Hb-A). The difference in the sedimentation coefficient between Hb-A (or Hb-E) and Hb-F may be explained as follows. Different workers[6,7,15] have recognized that hæmoglobin in solution is possibly a heterogeneous mixture. However, a single boundary is observed due to a rapidly established association-dissociation equilibrium. On this ground the difference in S-values between Hb-F and Hb-A represents a difference in the weight average molecular weight of the two mixtures.

PATHOLOGY

Effect of Thymectomy on the Induction of Skin Tumours by 3,4-Benzopyrene

Many tumours induced by chemical carcinogens[1] or viruses[2–4] have been shown to be antigenic in the syngeneic and even autochthonous host. The fact that antigenically 'foreign' tumours can grow progressively to kill their hosts suggests the existence of factors which compensate for the antigenic disadvantage of the tumour cells. Thus, perhaps, only tumours of weak antigenicity can progress whereas more strongly antigenic clones may fail to develop. Furthermore, tumour progression might be possible only when the host's mechanism for homograft immunity is either poorly developed, as in the new-born[5], or depressed as a result of irradiation[6] or of the chemical carcinogen itself. It is known that a wide variety of carcinogenic agents themselves depress various types of immune response, including the homograft reaction[6]. It has in fact been suggested that the biological *raison d'être* of homograft immunity may be to allow the body to eliminate antigenically foreign neoplastic clones as they arise and before they can spread[7].

An animal with a deficient immune mechanism might be a useful tool for the study of host resistance to spontaneous and experimentally induced tumours. Experiments performed in this laboratory have shown that mice thymectomized immediately after birth fail to reject skin grafts from foreign strains and even from rats[8]. Most of them, however, die from a wasting disease which develops within 4 months, the actual percentage of mice affected and the age at death varying with the strain. Thymectomy at 3 days of age is still associated with some reduction of the capacity for rejecting homografts but only when antigenic differences between donors and hosts are slight[8]. Furthermore, the number of mice dying from wasting disease is considerably reduced when thymectomy is performed later than 48 h after birth. We therefore decided to examine the susceptibility of mice, thymectomized at 3 days of age, to the carcinogenic activity of various hydrocarbons. Preliminary results in one system only are reported here.

Mice of a colony bred albino stock, derived originally from S. Schofield of Oldham, Lancs, were thymectomized or sham-operated 3 days after birth and painted from 5 weeks of age with 50 μg benzopyrene dissolved in 0·2 ml. acetone twice weekly for 20 weeks, the total dose being 2 mg. The solution was delivered on to the dorsal skin by graduated pipette after removal of hair by electric clippers. Other thymectomized and sham-operated mice were treated in an identical way but only with acetone. From 11 weeks onwards a weekly record was kept of the size and positions of all papillomas, and biopsies were performed on all tumours which reached a size of 12–15 mm in diameter. Survivors were killed at 40 weeks and all tumours more than 10 mm in diameter were examined histologically.

Table 1. Effect of Thymectomy on Incidence of Skin Papillomas induced by Benzopyrene

Group	No. of mice*	No. of mice with skin papillomas at following time (days) after first application of benzopyrene										
		70	80	90	100	110	120	130	140	150	160	170
Thymectomized	16	1	3	6	7	8	8	12	12	15	15	16
Sham-thymectomized	22	0	1	1	1	4	6	10	11	19	20	21

* Only papillomas which did not regress are shown.

The time taken for the mice to develop their first papillomas is shown in Table 1. It can be seen that by 100 days after the first application of benzopyrene almost 50 per cent of thymectomized mice had developed papillomas in contrast to only 5 per cent of mice in the sham-thymectomized control group. Table 2 indicates the number of papillomas which regressed and the number which became malignant in the two groups at various

intervals. Fewer papillomas regressed in thymectomized mice than in controls. On the other hand, more papillomas became malignant in thymectomized than in control mice. The total area of papillomas developing in each mouse at various intervals after painting is shown in Figs. 1–3. The histograms indicate that papillomas tend to develop and grow to a larger size earlier in thymectomized than in control mice. One mouse out of 12 thymectomized mice treated with acetone only developed papillomas. None developed in 12 sham-thymectomized acetone-treated mice.

TABLE 2. EFFECT OF THYMECTOMY ON PROGRESSION OF SKIN PAPILLOMAS INDUCED BY BENZOPYRENE

No. of days after first application of benzopyrene		No. of survivors	Total No. of skin tumours	No. of papillomas regressing	No. of tumours becoming malignant
120	Thymectomized	17	34	1 (3%)	—
	Sham-thymectomized	22	36	7 (20%)*	—
150	Thymectomized	16	123	6 (5%)	6 (5%)
	Sham-thymectomized	22	109	18 (16·5%)*	1 (1%)
180	Thymectomized	14	134	14 (10%)	16 (12%)
	Sham-thymectomized	20	189	33 (17%)	8 (4%)*

* $P < 0.05$

In considering these results, we are comparing carcinogenesis in two groups of mice: in one group the mice have had a depression of the homograft rejection mechanism from the neonatal period and may, therefore, be expected to allow neoplastic clones of altered antigenic constitution to grow freely; in the other group the mice initially had normal immune mechanisms but these may have become depressed progressively as a result of repeated application of the carcinogen. If we assume that some of the tumours arising in the present experiment are antigenic in their host and that benzopyrene depresses immunological capacity, we would expect thymectomized mice to show a higher incidence of tumours and a lower regression-rate, and differences between the two groups to become less with time. The results presented in fact indicate that tumours arise earlier in thymectomized mice, that the regression-rate is higher in the controls and that these differences are less later. These results are in harmony with the data obtained from rats thymectomized at birth and injected with polyoma virus[9]. Such rats are more sensitive to the oncogenic effect of the virus than are normal and sham-operated controls; they show a higher incidence of tumours and a prolongation of the neonatal period, during which they remain susceptible to

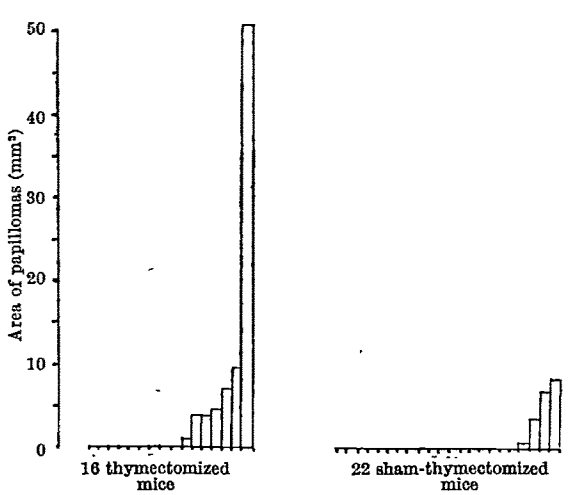

Fig. 1. Incidence and area of papillomas in mice 100 days after first application of benzopyrene. The difference in area of papillomas in controls and thymectomized mice is statistically significant ($P < 0.001$)

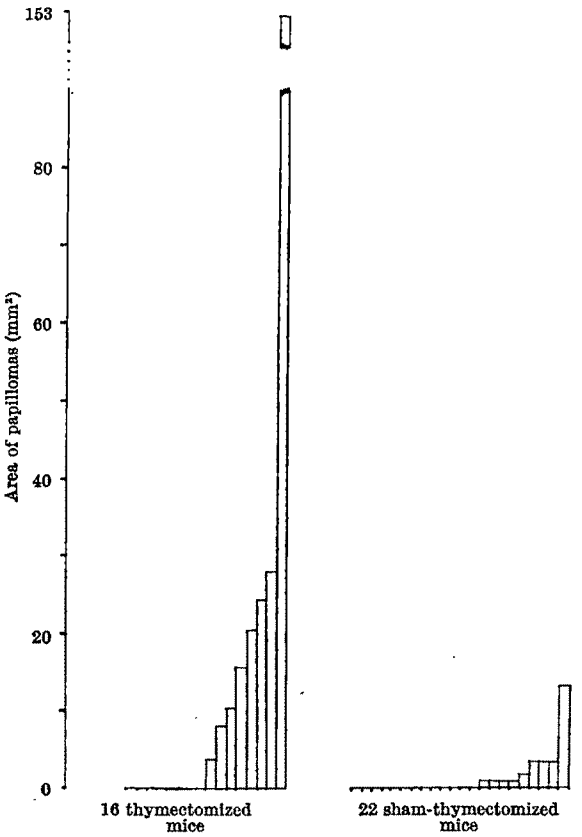

Fig. 2. Incidence and area of papillomas in mice 120 days after first application of benzopyrene. The difference in area of papillomas in controls and thymectomized mice is statistically significant ($P < 0.001$)

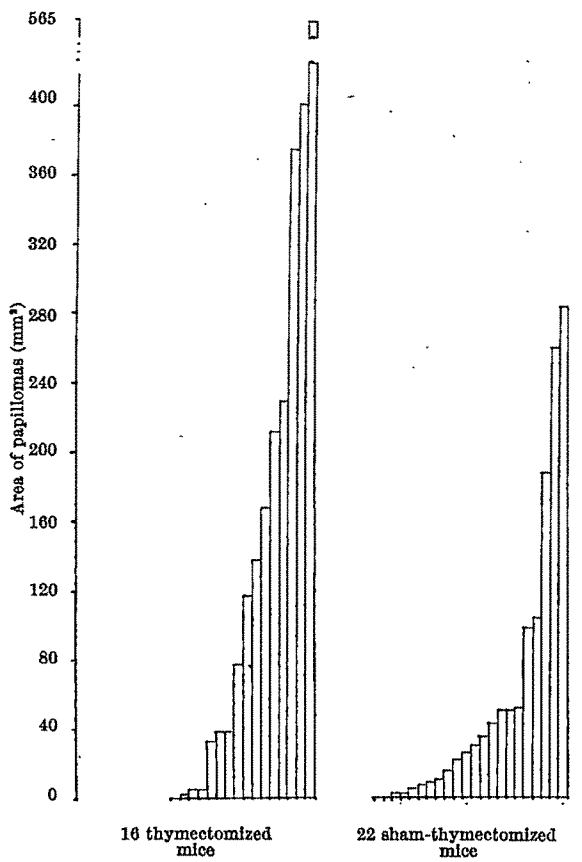

Fig. 3. Incidence and area of papillomas in mice 160 days after first application of benzopyrene

the oncogenic effect of the virus. It may be, therefore, that interference with the immune mechanism is an important pre-requisite for successful carcinogenesis.

Wine as Source of Iron in Hæmochromatosis

The belief that there is increased absorption of iron from a normal diet in idiopathic hæmochromatosis is based on assumptions of normal dietary iron during the time the disease is developing. Studies of iron absorption late in the disease have led to conflicting conclusions[1,2]. This communication directs attention to wine as a possible source of increased dietary iron in hæmochromatosis.

A close association exists between the use of alcohol and hæmochromatosis; 20–80 per cent of hæmochromatotics are alcoholic. It may be inferred that additional patients consume alcohol in lesser quantities. Increased tissue iron has been found in 40–80 per cent of patients with 'alcoholic' or nutritional cirrhosis in several countries of the world[3–5]. The amount of iron may frequently be as great as in hæmochromatosis.

Investigations of the iron content of alcoholic beverages from various countries reveals that wine, in contrast to distilled beverages, is a rich source of iron, chiefly in the ferrous form, with an average of 4·4 mg/l. in U.S. varieties consumed most commonly by alcoholics in Boston; an average of 6·2 mg/l. was found in 22 French varieties from Burgundy, Bordeaux, and Romagne; and 10–16 mg/l. in cider and wine from Rennes, France, where iron diseases are especially common.

The iron appears to be derived chiefly from pipes and equipment used in preparation of wine, and is well known to the wine industries[6]. The copper content of French wines is approximately 1 mg/l., derived from copper sprays of the grapes and from equipment. Prior to the Second World War the iron content of U.S. wines was considerably higher, up to 35 mg/l. From about this time attention was directed in the wine industry to lowering the iron content because it is an important contributor to the formation of sediment, and the U.S. market prefers sediment-free wines. Chronic alcoholics in Boston consume large quantities of wine in preference to distilled spirits because it is cheap; 2 l./day is not unusual and is probably a minimum figure. Chronic alcoholics in France consumed an average of 2·5–5 l./day, and 50–116 non-alcoholic controls drank 1–2 l./day in an investigation[7].

The normal Western diet contains 10–15 mg/day of iron, of which approximately 10 per cent or 1–1·5 mg/day is absorbed and excreted. If iron is added to the diet it continues to be absorbed[8], resulting in increased body stores. Hæmochromatosis is a disease of middle age, and is characterized by a body store of 20 g or more of iron in contrast to the normal 4–5 g. Absorption of 1·8 mg. of iron a day over the normal amount for 30 years, or of 2·5 mg/day for 20 years accounts for the quantity of body iron in hæmochromatosis. With absorption of 17·8 per cent[8] of dietary iron, consumption of 2 l. of particular brands of present-day U.S. wines would result in absorption of 1·8 mg of iron. Non-alcoholic Frenchmen in Rennes consuming 2 l. of wine with 16 mg of iron/l. and with 15·1 per cent absorption[8] would absorb 5 mg. Alcoholic Frenchmen in Rennes consuming 5 l./day of the same wine, assuming 12·6 per cent absorption[8] would absorb 10 mg. It is possible that absorption would decrease with increased body stores, but even assuming 10 per cent absorption this would alter the foregoing figures to 0·8 mg iron for 2 l. of U.S. wine, 3 mg for 2 l. Rennes wine, and 8 mg for 5 l. of Rennes wine. Consumption of 2 l./day of U.S. wine prepared prior to the Second World War, with its iron content 30 mg/l., would result, with an absorption of 12·7 per cent[8] in absorption of 7·6 mg iron, and with 10 per cent absorption in 6 mg.

Ingestion of iron and copper containing wine or other beverages can explain the characteristic features of hæmochromatosis, and is consistent with the concept that it is a variant of nutritional or 'alcoholic' cirrhosis or of the factors that lead to cirrhosis[9]. The occasional familial occurrence of the disease, and of elevated serum or tissue levels of iron in relatives is commonly presumed to be due to genetic inheritance. Detailed dietary histories and personal dietary analysis have not been carried out during the developmental years of the disease, however, nor in family members. A familial occurrence of elevated serum or tissue iron in the presence of ingestion of a common dietary substance such as iron obviously need not be genetically determined. In as much as the source of iron in wine appears to be from equipment used in preparation, other alcoholic beverages, particularly from early years when iron equipment was more prevalent, or 'home made' alcoholic preparations, might be a rich source. Other factors in cirrhosis, such as diet, pancreatic disease, and anæmias, could further enhance iron absorption[9] but need not be invoked. Additional sources of oral iron are non-prescription medical preparations taken commonly in many countries, including the United States. The amounts of iron in wine and in medicines are not harmful, even when accumulated in large quantities in the liver, and so are not contra-indicated, but an understanding of the source of iron in hæmochromatosis will clarify many controversial beliefs about the disease, and about iron metabolism.

RADIOBIOLOGY

A Fast-neutron Source for Radiotherapy

In a recent note, Lomer and Greene[1] have recommended the development of a 14-MeV fast-neutron source for radiotherapy. We feel that there are disadvantages to this approach. The relative biological effectiveness of fast neutrons is related to their linear energy transfer, which in turn varies inversely with the energy of the neutron[2,3]. It has been shown that cell-killing by 1–2-MeV neutrons (linear energy transfer, 50–60 keV/μ) is relatively independent of oxygen[3]. As the energy of the neutrons is increased, the effect becomes more oxygen-dependent[4]—30-MeV neutrons would have a linear energy transfer similar to 250-kV X-rays, and hence a similar oxygen-dependence. If one is to expect an improvement in the results of radiotherapy due to the relative oxygen-independence of the effect of fast neutrons, then one must attempt to use those neutrons the effects of which are relatively oxygen-independent; this cannot be claimed for 14-MeV neutrons (linear energy transfer 20 KeV/μ). A useful increase in effective linear energy transfer with depth of penetration in tissue has yet to be demonstrated: the neutrons will lose energy and become more densely ionizing but the γ-ray component of the total dose rises.

Lomer and Greene concede that in the *D–T* reaction, 14-MeV neutrons are produced isotropically and do not suggest how they intend to collimate a useful beam of neutrons for localized radiotherapy without introducing extensive γ contamination and lowering the average linear energy transfer of the beam. By contrast, the bombardment of a thick target in a cyclotron produces a beam of fast neutrons projected mainly forwards, and this demands less collimation[5]. Any desired neutron energy may be obtained by appropriate choice of cyclotron size to produce the required energy of bombarding particle. Since fast-neutron irradiation seems to offer the promise of improved tumour response[6], it deserves to be carefully tried using equipment which produces the energy of particle most likely to give this improved response. The choice of a machine which only produces the less-effective 14-MeV neutrons solely because it is less costly, would be a disservice both to the radiotherapist and to clinical science in general.

R. J. Berry
R. Oliver
E. H. Porter

[6] Fowler, J. F., Morgan, R. L., and Wood, C. A. P., *Brit. J. Radiol.*, **36**, 77, 115 (1963).

Berry, Oliver and Porter have ably restated the facts we attempted to summarize in the second paragraph of our letter, but do not appear to have grasped the need for a compromise between the desirable high linear energy transfer associated with low-energy neutrons and the desirable penetrating power associated with high-energy neutrons. We do not suggest that 14-MeV neutrons give the best compromise of this type, but merely that since they are obtainable from a relatively cheap and compact source, their usefulness is worthy of experimental evaluation.

We do not dispute that a cyclotron is a more versatile neutron source than a *D–T* generator, but we do claim that the merits of low cost and compactness of the latter are very relevant to radiotherapy. We would certainly not agree that economic consideration can be entirely dismissed, as Berry, Oliver and Porter seem to suggest, though their imputation that cost is our sole consideration is, of course, incorrect.

It is perhaps worth enlarging a little on the importance of compactness. In radiotherapy accurate direction of the beam at the tumour is a primary consideration, and this is best achieved by using a flexibly mounted radiation source so that the beam may be moved with respect to a comfortably placed patient, rather than the patient 'lined up' to the machine: compactness is thus important because it facilitates accurate treatment.

We are, of course, well aware that designing a neutron collimator is a problem, and the solution of this problem is naturally an important part of our development programme.

Furthermore, even if 14-MeV neutrons prove to have no biological advantage over megavoltage X-rays, the *D–T* source may still be competitive with high-energy X-ray units, in so far as there are reasonable grounds for believing that they will produce similar dose distributions inside a patient.

For these reasons, to talk of a "dis-service to science" (as in their last lines) displays an emotional reaction which, when speaking of a research project, is scarcely justifiable.

P. D. Lomer

Baldock, Herts.

D. Greene

Christie Hospital and Holt Radium Institute,
Manchester 20, Lancs.

Lomer and Greene have recently proposed the development of a source of monoenergetic 14-MeV neutrons for radiotherapy[1]. Berry, Oliver and Porter have commented in the foregoing communication that such neutrons would have too high an energy to give the advantage over X-rays of independence of the biological effect on oxygen concentration which has been found with lower energy neutrons.

There are two distinct aspects to this discussion. One is the discussion of the 'biological' properties of such a beam compared with those of X-rays. The other is a possible 'economic' advantage if simple, cheap apparatus could produce a beam of penetrating radiation, even if the biological properties are not different from those of X-rays.

I agree with Berry, Oliver and Porter's comment that 14-MeV neutrons would have too high an energy, and consequently would give rise to proton tracks in tissue having too low a linear energy transfer, to give a significant advantage over X-rays in respect of the oxygen independence[2]. There is little doubt that the optimum neutron energy for obtaining the best compromise[3] between oxygen-independence[4–6], requiring low neutron energies, and good penetration of tissue[7], requiring high energies, is (giving wide limits) between 3 and 10 MeV mean energy. The small doubt that remains is due to the lack of information about the degradation of neutron energy with penetration into tissue, but rough estimates make this appear extremely unlikely to give a useful gain in ionization density with depth in tissue for neutrons of higher energies. There would be no 'biological' advantage in using neutrons which are too fast to give an oxygen-dependence significantly different from that of X-rays. Indeed, there may be some dangers in doing so until further investigations have been carried out on the effects of fast neutrons on cartilage, connective tissues, and other structures[8]: such work is in progress on the Medical Research Council cyclotron at Hammersmith.

It is true that an 'economic' advantage over cobalt-60 or linear electron accelerator sources would arise if a beam of radiation having penetration and output similar to that of 4-MV X-rays could be generated from simple, cheap

apparatus, as envisaged by Lomer and Greene, even if the oxygen-independence were no better than for X-rays. The main problem is to obtain adequate output. An associated problem is to keep the γ-ray proportion small. Both problems are difficult for 14-MeV neutrons, since an effective collimator would have to be very long.

Even if these problems could be solved, the advantage would be economic rather than biological, at these linear energy transfers. It should not be confused with the fundamental advantage of oxygen-independence in radiotherapy, which can be expected on radiobiological grounds[4,5,9] to give improved cure rates, and which may be approached by a number of methods[2]. High-pressure oxygen breathed by the patient during X-ray treatment[10] or a beam of fast neutrons of optimum energy[8,11] (3–10 MeV) are the only two methods immediately available, although a beam of negative π-mesons has been suggested[12]. There is no virtue in building more sources of radiation of a relatively inefficient type (low linear energy transfer) just because they are cheap; their existence may displace, or obscure the need for, more effective beams of radiation.

It would be most useful if Lower and Greene could design a neutron generator using a lower energy exoergic reaction and giving an adequate output with a small proportion of gamma rays. Pending this development, it is important to remember that small cyclotrons are now commercially available in the United States for about £60,000 for 4·5-MeV, £100,000 for 6-MeV and £300,000 for 8-MeV deuteron energy. These prices are not so far above the costs of linear electron accelerators which are at present used for radiotherapy—but which do not give the biological advantage of oxygen-independence—that cyclotrons can be ruled out of consideration for radiotherapy in the future.

Influence of Fractionation on Clinical Response and Dosage in Radiotherapy

In general, the clinical and biological response to irradiation is directly proportional to the dose and inversely proportional to the length of time over which the total dose is administered—the so-called dose-time relationship.

In clinical radiotherapy by external irradiation, using beams of X- or γ-rays, the total dose has commonly been divided up into a variable number of fractions each of which is given daily (Sunday and often Saturday excluded), over a total period of several weeks.

By using these prolonged fractionated techniques, quantitatively larger doses can be administered to patients with safety than when the total dose is given in one treatment. Experimental and clinical observations in the 1920's, furthermore, led to the belief that such fractionation enhanced the greater differential destruction of malignant cells by irradiation, a conception open to some challenge in recent years[1].

Experimental work in mice has shown that in both a carcinoma[2] and a rapidly growing sarcoma[3] an interval of 48 h, between fractions of irradiation, gave better results than intervals of 12, 24, 72 or 120 h. Techniques reducing the number of fractions during courses of X-ray therapy, but maintaining the overall period of the treatment, have gradually been evolved in this Department since 1948. Initially this was applied to the treatment of the smaller skin tumours, for example, rodent ulcers, where even single treatments were found adequate in many instances[4,5]; with increasing experience the technique was extended to the treatment of some larger lesions and more extensive volumes of tissue, until a régime of three treatments a week, at 48-h intervals, was adopted in an appreciable number of patients.

Both in the experimental work in animals and in our clinical practice it was noted that a reduction had to be made in the total dose when it was given in a curtailed number of fractions if a similar biological effect was to be obtained. In pigs, doses given every other day require reduction by 15 per cent of the doubled daily dose if, over the same total period, the same degree of observable skin reaction is to be obtained as that found on daily fractionation[3]. Comparable results in the skin of pigs were found by Fowler *et al.*[6], who state that a reduction in dose of about 20 per cent is required when a change is made from 21 fractions to 9 fractions over a total time of 28 days.

The experimental results suggest that considerable improvement in clinical radiotherapy might be possible by adopting curtailed fractionation techniques. Before changing from a well-established method of treatment it is natural to look for any guide as to the best new method to adopt and, secondly, what the immediate and long-term consequences of such a change would be. Lack of information on these points has prompted us to report the following results at this stage, because we feel that they provide an adequate reassurance on which to base further clinical trials. A much fuller analysis of the cases is being undertaken and it is hoped to publish this at a later date.

We have found that reduction of about 15–20 per cent in the total dose is required when the number of fractions in which the treatment is given is reduced from five a week to three a week.

This conclusion is based on our observations in both small and large treatment areas, the former on the results of treating skin malignancies such as rodent ulcers. These represent small treatment areas, less than 4·5 cm diameter, irradiated at 60 kV, half-value layer 2·75-mm aluminium. The cases treated five times per week received a surface maximum dose of up to 6,000 r. in 10 fractions over 14 days and those treated three times a week received 4,800 r. in 6 fractions over the same 14-day period. These doses resulted in similar immediate skin reactions following treatment, and there was no significant difference in the late results between the two methods of treatment[5].

Consequent to the foregoing findings in small treatment areas, we extended the curtailed fractionation regime to larger treatment areas as required, for example, in radical irradiation following a mastectomy for carcinoma of the breast.

In this latter treatment our original method of irradiating the chest wall[7] entailed the use of beams of X-rays at 250 kV, half-value layer 1·75-mm copper, directed tangentially across the chest wall. The patients on the thrice weekly régime received an average tissue maximum dose of 3,600 r. in 12 treatments over 28 days, while those treated five times weekly received an average tissue maximum dose of 4,500 r. in 20 treatments over 28 days. These doses were arrived at, following adjustment, so that a similar immediate skin reaction resulted. Those receiving treatment five times a week were in-patients, whereas the others attended as out-patients and the difference in clothing may well have influenced the severity of the chest wall skin reaction resulting in the three times

weekly group receiving a slightly lower dose in order to maintain similar skin reactions in the two groups.

A large number of the cases assessed has been followed up for more than 10 years. At no time has there been any apparent difference in the late radiation effects, such as fibrosis, atrophy or telangiectasis, between the patients treated three times weekly and those treated five times weekly with the doses mentioned. Close observations at follow-up have not, so far, revealed that curtailed fractionation has apparently influenced survival times and recurrence free rates; it is hoped to publish with fuller details the results of some further investigations into this at a future date.

BIOLOGY

Effect of Certain Soil Organisms on the Eggs of Parasitic Roundworms

The influence of biological factors on the development and viability of eggs of parasitic roundworms (geohelminths) in soil has not yet been sufficiently explored. It is known that some fungi are able to attack free-living Nemathelminths[1–3]. It has also been shown that some fungi can attack larvæ of *Strongyloides* from horses and larvæ of *Trichostrongylides* from cattle[3]. Some fungi are also capable of inhibiting the development of eggs of ascarids *in vitro*[4]. Gudzhabidze and Preobrazhenskaya[5] performed experiments on *Ascaris* eggs by influencing them with micro-organisms, which had been isolated from the soil specimens from sewage farms. Certain species of actinomycetes and soil bacteria were capable of exerting a depressing effect on the eggs of ascarids.

I have attempted to ascertain whether in open fields the eggs of human parasitic geohelminths are influenced by organisms which are living in the soil and to what extent. I carried out my experiments in the following way: on the specimens of the soil with fæcal pollution (human or animal) I placed small piles of fertilized and unfertilized eggs of ascarids from pigs. Organisms from the soil to which the *Ascaris* eggs produced favourable conditions of life broke from the soil through the piles of eggs and profusely multiplied there. These organisms either inhibited the development of *Ascaris* eggs or even destroyed them.

On some piles of *Ascaris* eggs Acari and Collembola multiplied considerably. Acari: *Rhyzoglyphus* sp. (Claparède 1869), *Sancassania tschernyschevi* (Zachvatkin), *Annoetus ferroniarum* (Dufour 1939) and *Fuscuropoda marginata* (Koch 1939); Collembola: *Hypogastrura (Ceratophysela) denticulata* (Bagnall 1941), *Hypogastrura* (Hypogastrura) *vernalis* (Carl 1901), *Folsomia candida* (Willem 1902) and *Folsomia candida* var. *distincta* (Bagnall 1939). Acari from the family Acaridae (Tyroglyphidae) were especially capable of consuming a large quantity of ascarid eggs. For example, in one experiment 5 adult individuals of Acari were put on 0·5 g ascarid eggs. At the end of this experiment, which lasted 32 days, these Acari multiplied in 58 adult individuals and a very large number of larval stages. In the course of this experiment the Acari consumed 0·38 g of eggs.

a *b*

Fig. 1. Eggs of ascarids broken through by the fungus *Fusarium redolens* Wr.

Besides these soil animals various species of fungi and soil bacteria penetrated into the *Ascaris* egg piles. Some of these organisms destroyed the morphological structure of the eggs. Numerous experiments were made with isolated clear cultures of these fungi. The eggs were destroyed especially by two species of fungi: *Fusarium redolens* Wr. and *Cephalosporium* sp. Both these fungi have already been described by other authors as parasites on free-living Nematoda in the soil. These fungi penetrated the eggs, consumed their contents so that only deformed thin eggshells remained (Figs. 1*a* and *b*). The eggs were also destroyed by other species of fungi and even bacteria. The isolated organisms, however, soon lost their biological activity after having grown for a short time in the artificial medium.

In this communication I wish to direct the attention of parasitologists who are engaged in the problem of cleaning soil of eggs of pathological nematodes to the fact that the development and the length of viability of these eggs in the soil are influenced not only by physical and chemical factors but also by some animals and fungi which live in the soil.

I thank Dr. O. Fassatiová, Faculty of Natural Sciences, Charles University, Prague, for her assistance in identifying the fungi, Mr. J. Nosek, Virological Institute of the Academy of Sciences, Bratislava, for his assistance in determining the Collembola, and Dr. K. Samšinák, Biological Institute of the Czechoslovak Academy of Sciences, Prague, for his assistance in identifying the species of Acari.

Influence of Mechanical Damage on Opaline Silica Deposition in *Molinia caerulea* L.

In our microscopic investigations of opaline silica bodies in the leaves of a large number of British grasses[1], we have found that where leaves were already bruised or torn before being taken from the tiller or culm, the epidermal preparations made from them often showed abnormalities in the degree and pattern of deposition of silica. It was therefore decided to investigate the effects of various kinds of deliberate damage. *Molinia caerulea* was chosen for preliminary experiments because the silica pattern in this grass had been examined in some detail by us, and opal had been found in a variety of its epidermal

cells ranging in size from the intercostal short silica cells to the very large bulliform cells which are silicified erratically near the tips of some of the leaves[2].

Ten rooted clumps were potted singly in John Innes compost so as to provide thirty actively growing shoots, five to serve as controls and twenty-five for various damage treatments. The shooting leaves of actively growing tillers were subjected to five treatments: (i) pricking through the leaf blade with a fine needle at a number of points along its length; (ii) removing the apical portion by cutting off with scissors one-sixth of the blade; (iii) cutting off five-sixths of the blade; (iv) notching by making a transverse cut from margin to mid-rib in a position one-sixth of the way down the blade, and (v) notching in a similar manner five-sixths of the way down the blade. There were five replications of each of the five treatments.

A B

Fig. 1. Silica deposited in bulliform cells in damaged blades of *Molinia caerulea*. *A*, Treatment (ii); *B*, treatment (iv). (× 15)

After six weeks the treated leaves were removed and prepared for microscopical examination using successively ammonia and hydrogen peroxide[3]. None of the five treatments had produced any unusual development of the dumb-bell-shaped silica bodies characteristic of the costal regions nor of the small silica bodies of the intercostal areas. Both types are too small to be seen in Fig. 1. Three treatments, (i), (iii) and (v), produced no unusual development of silica in the bulliform cells, but the other two, where the damage was applied near the tip, produced deposition in these cells which was abnormal both in amount and distribution. The heavy silicification resulting from treatment (ii), namely removal of tip, was very pronounced in three, but completely absent from two of the replicates, and that resulting from treatment (iv), namely notching near the tip, was very pronounced in four but only slight in the remaining replicate. The phenomenon could be seen easily at low magnification. In Fig. 1*A* silicification of bulliform cells extends across the entire breadth of the blade. In Fig. 1*B* silicification is heaviest below the point of damage where it corresponds precisely with the width of the notch.

Fagan[4] working on *Dactylis glomerata* has shown that the silica content of the leaf increases by about 350 per cent in the withered tip as opposed to the lower green and non-withered portions of the blade. The present work suggests that certain types of mechanical damage can also be causes of excessive deposition of silica. These and other aspects of silica deposition are being investigated further by us. Among other considerations, they could well have a bearing on the recovery and subsequent palatability and digestibility of grass herbage after several partial defoliations such as would occur under any grazing system.

MICROBIOLOGY

Unlinked Loci affecting Related Biosynthetic Steps in *Pseudomonas aeruginosa*

It has been shown by Demerec, Hartman and others[1], that in *Escherichia coli* and *Salmonella typhimurium* it is usual for loci controlling related functions to be closely situated to each other on the chromosome and even for the arrangement of such loci to be the same as the sequence of biosynthetic steps concerned. The chief exception to this rule is the arginine biosynthetic pathway in which the controlling loci are distributed widely over the *E. coli* chromosome[2]. Using the technique of joint transduction, we have obtained evidence that in *Pseudomonas aeruginosa* this latter type of marker distribution of loci controlling sequential biosynthetic steps occurs with all the pathways so far investigated.

Joint transduction by phage *F*116 for the markers str (streptomycin resistance or sensitivity) and try (a marker controlling tryptophan biosynthesis) has previously been described[3]. These two markers show about 15 per cent recombination in sexual crosses[4] and are jointly transduced at a frequency of about 11 per cent. A collection of auxotrophic mutants of *P. aeruginosa* strain 2 was obtained by treatment with either manganous chloride or ethyl methane sulphonate and the mutants broadly classified by their requirements for amino-acids, purines, or pyrimidines.

Two methods have been used to determine the linkage relationships of the various markers.

(1) Phage *F*116 is propagated on a given auxotrophic mutant and is then used to infect bacteria of a second mutant strain. The infected bacteria are plated on minimal medium supplemented with the nutrient required by the mutant on which the phage was propagated. When the colonies so formed are replicated on to unsupplemented minimal medium, the frequency of joint transduction of the two markers is indicated by the ratio of the transduced colonies which can grow on minimal to those that cannot.

(2) For cases where method 1 is not applicable, for example, with transductions between mutant strains having identical requirements, some indication of the linkage between the loci can be gained by comparison of the transduction frequency obtained with one of the mutants using phage propagated on the other mutant, to the frequency obtained with phage propagated on prototrophic wild-type bacteria. If the two markers are cotransduced, the transduction frequency in the former case will be lower than that of the latter.

The strains, techniques and media used are the same as those described previously by Holloway *et al.*[3] and are similar to those commonly used in transduction studies. The results of a variety of transduction tests are shown in Table 1.

It is seen that there is no joint transduction of markers controlling related biosynthetic steps. The joint transduction of these markers with other unrelated markers shows that linkage can be revealed by this type of experi-

Table 1. JOINT TRANSDUCTION IN *P. aeruginosa* STRAIN 2 BY PHAGE *F*116

* Marker for streptomycin resistance or sensitivity.
† Linkage relationships determined only by method 2.

ment. Similar results have been obtained with groups of mutants affecting other pathways, including mutants having requirements for histidine, leucine, arginine and isoleucine plus valine, in these cases our conclusions being based largely on data obtained by method 2.

It seems reasonable to conclude that in contrast to the Enterobacteria, this lack of grouping of related loci on the chromosome is of general occurrence in *Pseudomonas*. This finding may have interesting implications in relation to the mechanism of genetic control of enzymatic reactions in this organism[5].

This work was supported jointly by the International Atomic Energy Agency (contract No. 86) and the Australian Atomic Energy Commission.

Polysaccharide Fractions and Transformations in *Rhizobium*

OUR interest in the composition of rhizobial gums[1,2] led us to attempt transformations using, first a preparation based on that of Ljunggren[3] and later the cruder, and therefore deoxyribonucleic acid-rich, fraction used by Lange and Alexander[4]. In the first case we aimed at restoring virulence to avirulent strains of clover *Rhizobia*, including two used by Ljunggren, but with *R. trifolii*, *SU*297/31 as the source of 'polysaccharide'. In the second we attempted a wider transformation, similar to those reported by Lange and Alexander, between clover and lucerne. In the latter we included a specially prepared deoxyribonucleic acid fraction as an additional treatment.

In no case have we been successful in obtaining transformation, and an experience we had in our attempt to repeat Lange and Alexander's method points to what we believe to be a possible weakness in their evidence. In that case an aliquot of the crude clover polysaccharide, when plated directly on yeast mannitol agar, yielded a number of *Rhizobia*-like colonies. These were able to nodulate the clover host and were serologically indistinguishable from the donor strain. A puzzling feature was that there were no nodules formed when parallel aliquots of the same polysaccharide solution were added to the clover host. We believe, however, that we have demonstrated that a few rhizobial cells were able to survive what appears to have been a drastic chemical treatment.

The element of doubt which this possibility introduces into work of this nature recalls the need to demonstrate a mixed genome in 'transformed' cells, partly derived from donor and partly from recipient (c.f. ref. 5). Evidence as to the persistence of genetic markers of the recipient strain in a culture, transformed in respect of its symbiotic capacity, is strangely lacking with *Rhizobium*. It is possible that the workers concerned already have direct evidence that will permit distinctive characteristics of the recipient to be identified in the symbiotically 'transformed' culture, or that they are in a position to investigate further the transformed cultures they already hold. Certainly such a demonstration can be regarded as a prime requirement for the validation of claims of this nature.

ENTOMOLOGY

Penetration of Pyrethrin I labelled with Carbon-14 into Susceptible and Pyrethroid Resistant Houseflies

As part of a wider investigation into the causes of insecticide resistance in a strain of house flies (*Musca domestica*), which show resistance to both DDT and the pyrethroids[1], specifically labelled (^{14}C)-pyrethrin I has been used to examine penetration of this insecticide into these insects.

(^{14}C)-pyrethrin I, labelled in the *cyclo*propane ring adjacent to the ester linkage, was prepared by the esterification of (^{14}C)-(±)-*trans*-chrysanthemum monocarboxylic acid with (+)-pyrethrolone. The alcohol was isolated from natural sources by Elliott's method[2]. The (^{14}C)-acid was prepared from (2-^{14}C)-glycine by the general route of Harper[3] with suitable modifications to the semi-micro scale; in particular, the separation of the mixture of *cis* and *trans*-chrysanthemum acids was carried out by fractional precipitation (infra-red control). Because of the small quantity of material available the (±)-*trans*-acid could not be resolved and so the final product was a mixture of natural pyrethrin I and one of its diastereoisomers, henceforth referred to as (^{14}C)-'pyrethrin I'.

Sub-lethal quantities of (^{14}C)-'pyrethrin I' in acetone were then applied by topical application to batches of flies of three strains: first, a susceptible strain (Fig. 1 *A*), secondly, a Swedish resistant strain[1] (Fig. 1 *B*), and thirdly, a colony of the Swedish resistant strain which had been allowed to revert to 'almost susceptible' by removing the pyrethroid selection pressure (Fig. 1 *C*). At increasing increments of time, batches of the flies were killed and the unabsorbed insecticide was washed from the flies and the containers with light petroleum, b.p. 40°–60°, and the combined washings were concentrated to dryness *in vacuo* and the weight of (^{14}C)-'pyrethrin I' was determined by a scintillation counting technique. A control experiment showed that the washings did not remove (^{14}C)-'pyrethrin I' already absorbed.

The results from these experiments are shown in Fig. 1, curves *A*, *B* and *C*. It would appear from these results that penetration into the resistant strain is significantly slower than into the other strains. No attempt was made to measure directly the loss of 'pyrethrin I' by excretion. Radioactivity recovered from the containers alone prob-

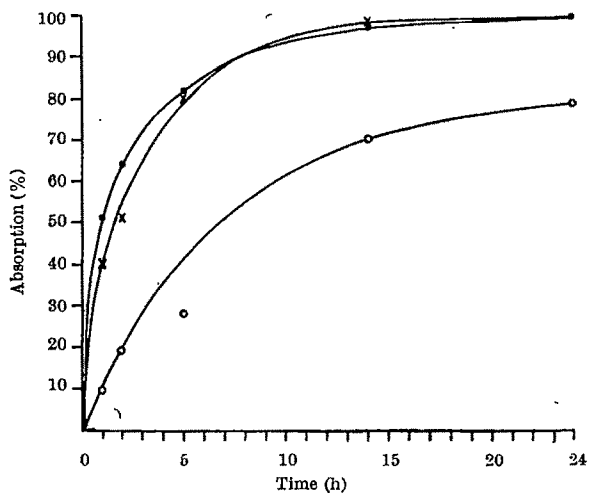

Fig. 1. ●, *A*; ⊙, *B*; ×, *C*

ably represents excreted (^{14}C)-'pyrethrin I' and its metabolites plus material lost from the flies by mechanical causes. In some cases this was assayed separately. The amounts recovered from the susceptible and reverted strains were negligible (about 1 per cent); however, in the resistant strain 9 per cent of the applied dose was in the containers after 14 h. This is probably due to mechanical loss, a function of reduced penetration which retains a large quantity of the insecticide on the outside of the flies for long periods. In any event, the amount recovered does not invalidate the differences shown in Fig. 1.

Both the susceptible and reverted strains were paralysed but later recovered after dosing, in contrast to the resistant strain which appeared unaffected. It may be argued because of this that penetration is facilitated by intoxication in the affected strains. To test this, susceptible and resistant flies were dosed with (^{14}C)-'pyrethrin I' at a very low level, where the susceptible strain was not outwardly affected, and it was found that after 2 h 65 per cent of the insecticide was absorbed by the susceptible strain and only 28 per cent by the resistant strain. This is in fairly good agreement with the results obtained using the higher dose-level (cf. Fig. 1).

It must therefore be concluded that there is a definite correlation between the rates of absorption of (^{14}C)-'pyrethrin I' and pyrethroid resistance in the strains studied here.

We thank Miss H. Inglis and Mr. T. Markes for assistance.

Sound Signals and Alternation Behaviour in *Pholidoptera*

The classical work of Regen[1] on the effect of artificially produced sounds on the stridulation behaviour of *Pholidoptera* (= *Thamnotrizon*) *aptera* (Fab.) has prompted similar work on the related British species *Ph. griseoaptera* (De Geer), with the view of clarifying our understanding of the factors involved in the alternation 'singing' of males and the response to sound by females. There appears to be some confusion in the literature about the conditions under which Regen induced his insects to 'sing' in alternation with artificial signals. The widely accepted view[2,3] is that he was able to obtain this response only from newly moulted adults which had not already learnt to sing in concert with other males. In fact, Regen points out that young males do not alternate at all until they have 'sung' together for some time and his experiments did not begin until they had started to alternate for long periods. There seems to be little evidence that his earlier failures, with older males, were due to learning by the insect, and other work in this field[4,5] supports the view that any recognition of the specific 'song' is due to inborn mechanisms.

The alternation 'singing 'of *Ph. griseoaptera* males is simpler and less regular than that of Regen's insect and consists of single chirps of approximately 0·05-sec duration made up of three or four syllables (wing movements). The interval between alternate chirps is in the order of 0·2–2·0 sec. It is relatively easy to induce them to alternate with such varied sounds as the note of a Galton whistle, pure tones from a signal generator, and hissing sounds made between the teeth. In a series of experiments three males were kept in a cage with a number (4–7) of females. Between experiments, alternation appeared to be similar to that observed in the field. During experiments, it was quite usual for one male to alternate with the artificial signals for a time and then for another to take over.

Some of the most interesting results were obtained when the sound used was long in comparison with the chirp of the insect. If successive periods of sound and silence of approximately 1 sec in duration were used, the insects alternated with the sound and scarcely ever interrupted it.

Fig. 1 is an oscillogram taken from such a sequence in which there were 137 replies to 144 signals. A morse key was used in this experiment and transients were produced both at make and break. When the length of the signals and the interval between them was increased, the insects interrupted the signal more often. Nevertheless, even when the periods used were as long as 15 or 30 sec, stridulation occurred more often during the silent periods than during the signals (in all of 12 χ^2 tests $P < 0{\cdot}01$). The frequencies used varied from 10 to 30 kc/s and the intensities varied from 60 to 90 db (relative to 0·0002 dynes/cm^2). Fig. 2 shows the frequency distribution of chirps during 24 min of a trial using alternate periods of 15 sec and a sound of 15 kc/s and 85 db. It will be seen that a large number of the emissions occurred during the first second after the end of the signal and this result has been confirmed in seven other trials where the chirp distribution was recorded. In three of these, the silent periods were obtained by placing a cushion over the loudspeaker and in the others a morse key was used as make and break. Both methods gave similar results, in spite of the fact that the cushion method produces a signal without any sharp transients (Fig. 3). This is in contrast with the work of Busnel *et al.*[6] where transients were found to be important.

These preliminary results suggest that artificial sound signals function both as releasers and inhibitors of the stridulation of *Pholidoptera*. A similar inhibition has been noted with *Ephippiger*[6]. The tendency of the insects to

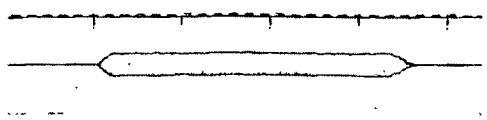

Fig. 3. Oscillogram of a 15 kc/s 85 db signal released and stifled by moving a cushion over the loudspeaker. Time marker 1 per sec

stridulate directly after the end of the signal may be due solely to the removal of the inhibition, or there may be, in addition, a direct response to some characteristic of the signal. Further work is being carried out to investigate these possibilities.

I thank Mr. W. B. Broughton and Dr. D. R. Ragge for their help and criticism.

CYTOLOGY

Corrected Chromosome Numbers for *Spartina* × *townsendii* and its Parent Species

Intensive cytological investigation of *Spartina*, carried out in the Department of Botany, University of Southampton, has revealed chromosome numbers which are not in agreement with those of Huskins[1] and Church[2,3].

In the classical case of *S.* × *townsendii* and its putative parents it will be recalled that chromosome numbers were previously given by Huskins as $2n = 56$ for *S. maritima* (Curt.) Fernald (formerly *S. stricta* (Ait.) Roth.) and $2n = 70$ for *S. alterniflora* Lois., the summation of these numbers, namely, $2n = 126$, being reported for the amphidiploid, then identified as *S.* × *townsendii*. Although these observations numerically accord well with each other in constituting the hybrid origin of *S.* × *townsendii* they nevertheless create an anomalous situation in the cytology of the Gramineae as a whole. The chromosomes of *Spartina* are very small and it is an established fact that small chromosomes and a basic number of 7 are not coincidental in the family[4,5]; small chromosomes are usually associated with $x = 9$, 10 or 12. In addition, the base of 7 is unusual in the tribe Chlorideae, in which *Spartina* is often included, where most genera have $x = 10$. This apparently paradoxical situation is resolved by the present results.

Counts of *S. maritima* from 6 localities on the south and east coasts of Britain show it to be a species with $2n = 60$. *S. alterniflora* Lois. plants, surviving as relics of a one-time much more extensive distribution of this species last century[6] in Southampton Water, have $2n = 62$ $(60 + 2)$. *S.* × *townsendii*, the sterile natural F_1 hybrid between these species, has been generally overlooked until recent years but still survives in large quantity at Hythe in Southampton Water. It has $2n = 62$. Some of the amphidiploid plants (previously known as *S.* × *townsendii*, but at present officially nameless) have $2n = 124$. Other plants of the amphidiploid type have $2n = 120$ and 122, respectively. Plants which appear by their morphology and chromosome number to be natural back-cross derivatives are found growing in the vicinity of the F_1 hybrid in Southampton Water, thus adding significantly to the evidence for hybridity. *Spartina glabra* Muhl. (another form of *S. alterniflora* sometimes known as *S. alterniflora* var. *glabra* (Muhl.) Fern.), introduced to Britain from the United States by F. W. Oliver in 1924, also has $2n = 60 + 2$ ($2n = 56$ according to Church[3]) and a regular meiosis.

Chromosome investigations have been extended to include the North American species of *Spartina* and the existence of a basic number of 10 is substantiated by counts of *S. pectinata*, which proves to have $2n = 40$ in two introductions from North America at Kew. *S. alterniflora*, received from Quebec, Canada (coll. Hamel), has $2n = 62$, similar to both the introduced forms of this species already in Britain. Other species are now being investigated. Gould's[7] count of $2n = 40$ in *Spartina spartinae* from Texas is further evidence in support of the base of 10.

It is clear that these data do not deny the hybrid nature of *S.* × *townsendii* or its precise parentage, although they make the cytological support for its origin slightly less acute than hitherto. *Spartina* × *townsendii* thus remains a plant of outstanding evolutionary significance by virtue of its natural origin by hybridization and chromosome doubling, resulting in a highly successful new 'species'. It is perhaps the most well-known and now substantiated example of natural species formation of this type and one of the few cases of its kind which has actually been observed to occur in a known locality rather than inferred entirely by indirect observations.

Spartina is certainly not unique in having wrong chromosome numbers reported for it. The *Chromosome Atlas*[8] reveals many genera in which numbers are uncertain, and doubtless many more anomalies exist but are as yet undetected. Perhaps the most well-known case of error in chromosome number is that of man, formerly thought to have $2n = 48$ chromosomes and, afterwards, from more intensive study and greater familiarity with the karyotype, shown clearly to have $2n = 46$ (ref. 9).

Because of its former chromosome numbers and supposed base number of 7, *Spartina* has not accorded satisfactorily with other genera of the Chlorideae and, indeed, its separation from the tribe has been proposed by various authorities[10]. This uncertain situation is now resolved by the new numbers, which bring *Spartina* into line cytologically with other members of the Chlorideae.

Analysis of Tritium-labelled Human Chromosomes and Sex Chromatin

It has been shown[1,2] that differential DNA synthesis in tissue culture may be studied by the incorporation of tritiated thymidine, followed by autoradiography of the labelled chromosomes. Grain counts have been made on human chromosomes labelled at the end of DNA synthesis, but the high grain density over the late-replicating *X* often obliterated morphology[3]. Asynchronous DNA synthesis has been demonstrated within human interphase nuclei[4]. An area of differential labelling was shown where the sex chromatin body might be expected to be present; but it was reported that the heavy concentration of grains made it difficult to determine whether an underlying body was present.

A method is described here which enables detailed examination of those structures which are obscured by a heavy concentration of silver grains. This method has been used to demonstrate and study the late-replicating *X* chromosome, an 'isochromosome *X*', and the sex chromatin body in the interphase nucleus of cells grown in tissue culture.

Fibroblasts from human skin and leucocytes from human blood were cultured by modifications of the standard methods[5,6]. 'Flash-labelled' chromosome preparations were made by adding tritiated thymidine (specific activity 1·41 c./mM, Radiochemical Centre, Amersham) to give a concentration of 1 μc./ml. of medium. The culture was incubated at 37° C for 10 min and the cells washed with, and re-incubated in, medium which contained excess thymidine (100 times the molar concentration of the tritiated thymidine). 'Long' labelling was performed by adding tritiated thymidine to give a concentration of 0·2 μc./ml. of medium. After the usual 'Colcemid' (Ciba) and hypotonic treatment, the cells were fixed at intervals varying between 4 and 11 h after labelling. Chromosome preparations were made by the air-dry method and stained with lacto-acetic orcein. The slides were taken from the stain, through 'Cellosolve', to water. If they were not required immediately for autoradiography, they were left to air-dry.

Each slide was covered with a film of 'Vinalak', which is a synthetic resin dissolved in a volatile solvent immiscible with water. A small drop of the lacquer was allowed to fall on to the surface of clean, distilled water, where it spread and formed a very thin film of resin. The slide, with cells uppermost, was brought up under the film and withdrawn from the water, carrying the film with it. As the slide was lifted from the water it was tilted at an angle of about 20° to the water surface, so that one long edge emerged, allowing the water to drain from between the film and the slide. The slide was left to dry at room temperature. Kodak '*AR* 10' autoradiographic stripping film was applied to the slide at 25° C (ref. 7), and it was exposed for 7–14 days. During photographic processing it was important to prevent the stripping film from floating off the slide. This was done by placing a clean slide at the back of the prepared slide and two 1-in. glass squares at either end and in front of the prepared slide; the whole was held together by two rubber bands. During processing, the slide was kept horizontal. All photographic solutions were at 18° C and, after 5 min development in Kodak '*D*-19*b*' and a 5-sec rinse in water, the slide was placed in 'Ultrafix', diluted 1 : 4 with water and with 1 : 20 hardener added. It was fixed until clear and then for half the time again. The slide was then washed for 1 min in each of six changes of tap water, followed by one wash in distilled water. It was left to dry horizontally. These precautions limited displacement of the stripping film.

The dry preparation, after careful removal of the retaining glasses and rubber bands, was mounted in 'Euparal' for examination. After photographic record, the coverslip and film were floated off by soaking in 'Euparal' essence, leaving the lacquered preparation undamaged. The lacquer has a negligible effect on resolution but, if desired, it may be removed by taking the slide through 'Cellosolve' to xylol, and leaving it in xylol for 12–24 h. The cells may then be mounted in Canada balsam.

For the study of the sex chromatin body, fibroblasts from human skin were cultured on cover-slips[8]. Labelling was performed by adding tritiated thymidine to give a concentration of 0·2 μc./ml. of medium, and the cells fixed at intervals, varying between 30 min. and 5 h after labelling. Each coverslip was stained with cresyl fast violet acetate[8]. After staining, the cover-slip was destained for about 1 min in water. It was left to dry before being

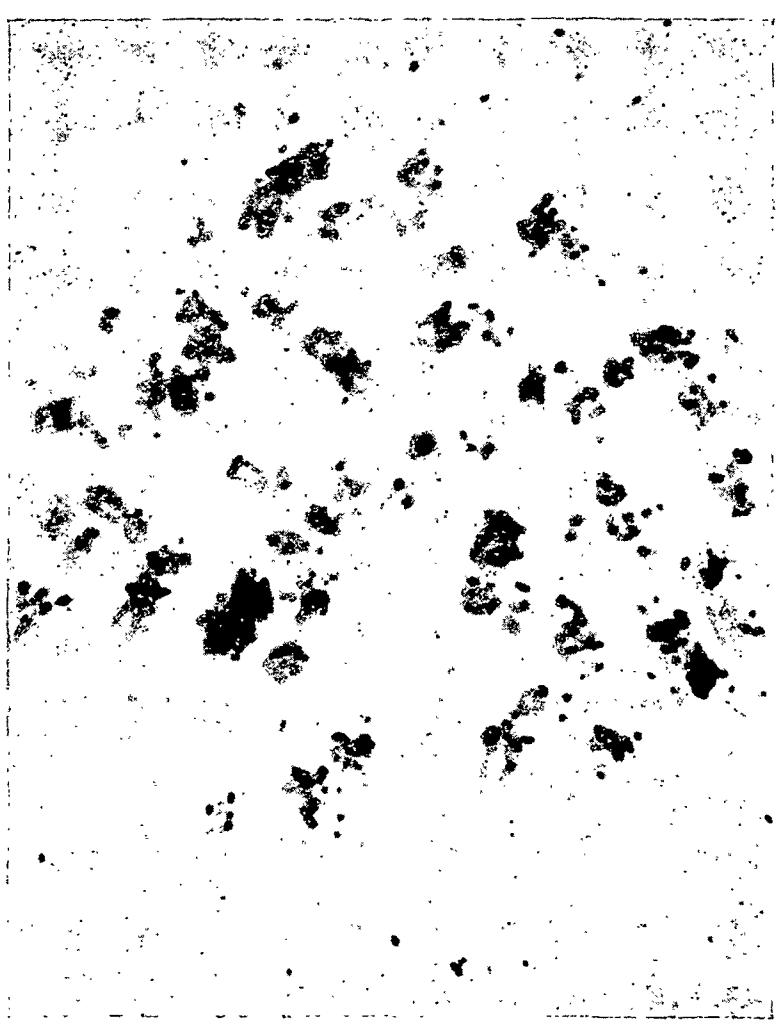

Fig. 1. Metaphase plate from human peripheral blood culture, after a 4-h 'long' labelling period in tritiated thymidine. This cell is from an individual with a normal female karyotype. Several chromosomes are obscured by a high grain density (× *c.* 2,500)

chemical composition of the DNA of the gene-groups with respect to the action of the mutagens.

The usual picture of the genetic material is that a gene contains a chain of about 10^3 nucleotide pairs, that there are 4 types of nucleotides, that DNA molecules of one type of organism do not differ grossly in the nucleotide ratio, and that most mutations change only one nucleotide pair in the DNA. If the mutability of a nucleotide type by a certain mutagen is determined by the structure of the base alone intergenic electiveness could scarcely appear since the fluctuations of the base ratio between genes or gene-groups would have to be very high. Therefore, this electiveness indicates that the mutability of a base depends very probably also on the neighbouring bases. If—as a minimum—only the 2 neighbouring bases are essential, the mutability of a site ('hot', 'warm' or 'cool' spot, etc.) would be determined by a base triplet.

Sixty-four such triplet types are possible, if the direction of the sequence along the DNA strand is essential, and 40 triplet types, if it is unessential for the mutability (for example, CAT = TAC). A gene of 10^3 nucleotides could therefore contain about (1,000 : 50 =) 20 triplets of the same type with large fluctuations of their numbers (and locations) between different genes depending on the ratio and pattern of the bases and the length of the genes. If the triplet types are different in their stability against mutagens a certain degree of electivity due to such fluctuations would then already be possible. But, in addition, mostly a considerable portion of mutations (base changes) is lethal or does not change the phenotype appreciably. In *Neurospora*, for example, 3/4 of the X-ray mutations of the ad-gene are found to be recessive lethals[8]; in phages the ratios of lethal to mutation hits by mutagens are high (Table 1). On the other hand, several mutations at different sites in the rII-region of phage *T*4 are reported to give wild phenotype[10]. Because of such lethal or intraphenic base changes, undetectable by the methods used, the number of hot spots for visible mutations would be further reduced to only a few per gene. This agrees with the finding of 2–5 strong hot spots per rII-gene of phage *T*4 (ref. 3).

Supposing this to be true for most genes the fluctuations in average mutation rate per gene or gene group are high when a mutagen attacks preferentially one type of base triplet. This would lead to the gene-group electivity observed.

PSYCHOLOGY

Electroencephalogram Alpha-activity during Mild Vestibular Stimulation

Previous reports have indicated that nystagmus resulting from vestibular stimulation is significantly influenced by instructions given to subjects regarding their mental activity[1–4]. In addition, under some conditions, nystagmus appears to reflect the subject's state of alertness more clearly than electroencephalogram (EEG) patterns[2]. There has been recent interest in the relation of arousal to EEG activity[5] and in the relation of EEG patterns to vestibular stimulation[6]. This report, bearing on both these interests, presents EEG findings obtained under different sets of instructions during repeated rotational stimulation. In addition, these new EEG results are here correlated with previously reported[1] nystagmus scores.

Eight men, aged 18–25 years, were tested on each of 5 consecutive days. The first session consisted of 4 practice trials, each under a different set of instructions. The remaining 4 (experimental) sessions each consisted of 6 trials. For all experimental trials on one day, subjects were given a single set of instructions. Tasks included: (*a*) silent arithmetic calculation; (*b*) signalling subjective rotatory experiences; (*c*) temporal reproduction of sound stimuli; (*d*) engaging in reverie. A counterbalanced order of task presentation was established such that 2 subjects were assigned to each of 4 orders of presentation. Rotation trials were conducted in total darkness with 15-sec periods of acceleration and deceleration (4·5°/sec²) separated by 2 min at a constant velocity. More detailed explanations of the tasks, rotatory conditions, and the method of scoring nystagmus data may be found elsewhere[1].

Subjects selected had no history of labyrinthine disorder, and no previous experience in vestibular experimentation. Five electrodes were used with each subject: a parieto-occipital pair for the EEG; a pair located at the outer canthi for the horizontal component of eye movements; a ground electrode. Signals were transmitted through slip-rings to an Offner Type *T* electroencephalograph situated in the adjoining control room.

Eye-movement scores were obtained by summing the amount of slow-phase eye displacement for 30-sec periods beginning with the onset of the stimulus. For the same time period, the number of seconds occupied by alpha activity was tabulated. Analyses of variance indicated that the instructions produced no significant differences in alpha activity, but that nystagmus output was significantly influenced ($P < 0{\cdot}001$). Application of *t* tests to the nystagmus data showed that mental arithmetic tasks resulted in significantly more ($P < 0{\cdot}05$–$0{\cdot}001$), and reverie tasks in significantly less ($P < 0{\cdot}01$–$0{\cdot}001$) nystagmus than each of the other 3 sets of instructions[1]. Table 1 contains mean results: (*a*) for all subjects; (*b*) for those subjects with high alpha output. The results are presented according to tasks, sessions and trials.

In spite of gross changes in nystagmus output as a function of the tasks, there was no apparent relation between alpha activity and amount of nystagmus for any given subject. However, 2 of the 3 subjects who displayed very little alpha produced the least overall amounts of slow-phase eye movement.

Representative examples of obtained EEG and nystagmus tracings appear in Fig. 1. It should be noted that some subjects will yield even less eye-movement under the reverie condition than is evident in this figure[1].

Makarian and Koreshkov[6] have indicated that vestibular stimulation induced by vigorous rotation (up to 30 r.p.m.) caused EEG changes. They reported increased beta activity, a lowering of alpha amplitude, and the appearance of asynchronous waves sometimes accompanied by slower undulations. Repeated rotation resulted in adaptation, particularly in individuals with low vestibular sensitivity. Our results (which do not include amplitude measurements) show no increased slow activity. There was no relationship between vestibular sensitivity, as measured by nystagmus output, and alpha activity. Further, there was no significant trend toward change in the amount of alpha activity either within a given session of 6 trials, or from day to day. However, it should be noted that the lowest average alpha output

Table 1. Mean Slow-Phase Nystagmus Output and Mean Number of Alpha Seconds per Subject for 30-sec Periods beginning with the Onset of a Rotatory Stimulus (4·5°/sec² for 15 sec).

occurred during the acceleration portion of the mental arithmetic trials (Table 1). The differences noted between our findings and those of Makarian and Koreshkov may be due to differences in electrode placement (they used temporal-occipital leads), in rotary velocity, or in subjects (instructions and prior experience).

Using caloric stimulation, Lidvall[7] recently reported no changes in EEG activity, although nystagmus output varied. In addition, he noted that alpha-blocking rarely occurred, and was never marked, when the vestibular stimulus was introduced. Our results and an earlier report[2] are in agreement with his observations.

That the tasks produced striking behaviour differences is clear from the nystagmus data. However, whether subjects were relaxed, attending to rotatory sensations, attending to external auditory signals, or doing mental arithmetic, alpha activity continued at the same rate during periods of sensory stimulation (acceleration and deceleration). These results lend support to the findings of Mulholland and Runnals[5] who, using attention-sets and "recurring complex alerting" (responding to a recurring signal by giving a report), indicated that " . . . (alerting) processes showing little relation to alpha suppression were continually activated from *within* (after an initial starting signal) and were *enduring*". Alpha suppression appeared when subjects were given an external signal and were required to present a verbal report. That the subjects in this investigation showed no alpha suppression to the tonal stimuli (external signal) might be accounted for by their set (estimating signal duration), uninterrupted by verbal reports. Mulholland and Runnals suggest the need for a qualification of the classical alpha-attention hypothesis "in terms of a particular kind of attention process or behaviour," and that " . . . the classical . . . hypothesis refers to a special case, that is, transitory alerting to an external signal".

The results obtained in this investigation also suggest that: (*a*) under some conditions, EEG monitoring is a less sensitive index of a subject's state of alertness than are vestibularly induced eye movements. This confirms a previous indication[2] and is similar to results obtained from new-born infants by Pendleton and Paine[8]. The latter have observed that " . . . the absence of vestibular nystagmus seems one of the most sensitive signs (of some alteration in the state of consciousness) in the newborn. It changes earlier with approaching sleep than do electroencephalograph tracings or respiratory rates and rhythms". (*b*) In addition, the simple monitoring of eye movements in given situations (for example, during air- or space-vehicle manœuvres) without some knowledge of the mental activity-level of the subject may give "false negatives" in judging the presence or degree of possible vestibular involvement. The marked differences in vestibular response depicted in Fig. 1 underline the importance of the mental state of the subject.

The results were obtained while we were at the U.S. Army Medical Research Laboratory and Ireland Army Hospital, Fort Knox, Kentucky.

FORTHCOMING EVENTS

Sunday, September 1—Wednesday, September 4

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE (at Aberdeen)—Continuation of 125th Annual Meeting.

Sunday, September 1

At 11 a.m.—Service in the West Church of St. Nicholas, Union Street. Minister: The Reverend Anderson Nicol, M.A., J.P. Preacher: The Reverend Prof. John M. Graham, D.D.

Monday, September 2

At 10 a.m.—Prof. J. H. Taylor, F.R.S.: "Some Aspects of Diagenesis", Presidential Address, Section C).

At 10 a.m.—Prof. T. Wilson: "The Price of Growth" (Presidential Address, Section F).

At 10 a.m.—Mr. Peter Opie: "The Tentacles of Tradition" (Presidential Address, Section H).

At 10.10 a.m.—Prof. H. M. Steven: "The Beneficent Forest" (Chairman's Address, Section K*).

At 2 p.m.—Dr. J. N. Murrell: "Colour and Chemical Constitution" (Kelvin Lecture).

Wednesday, September 4

At 10 a.m.—Dr. L. Wolpert: "Growing in a Definite Shape" (Darwin Lecture).

Wednesday, September 4

INSTITUTE OF PETROLEUM (at 61 New Cavendish Street, London, W.1), at 5.30 p.m.—Mr. R. Farley and Mr. D. J. Ray: "The Design and Operation of the Pilot Scale Plant for Hydrocarbon Synthesis in the Slurry Phase".

Wednesday, September 4—Friday, September 6

INSTITUTE OF PHYSICS and the PHYSICAL SOCIETY (at the University of Manchester)—Conference on "Low and Medium Energy Nuclear Physics".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT (with practical experience in freshwater biology or a degree or equivalent qualification) to Dr. T. B. Reynoldson, Reader in the Department of Zoology, to work on the ecology of freshwater triclads—Dr. T. B. Reynoldson, Department of Zoology, University College of North Wales, Bangor, North Wales (September 7).

LECTURER IN THE DEPARTMENT OF SOCIOLOGY—The Secretary, The University, Edinburgh (September 7).

ASSISTANT LECTURER, Grade III (with a degree in biochemistry) IN BIOCHEMISTRY—The Registrar, The University, Senate House, Bristol 2 (September 11).

LECTURER, Grade II (with a degree in engineering and at least five years approved industrial experience) IN MECHANICAL ENGINEERING at the School of Mines and Industries, Ballarat, Victoria, Australia—Council for Technical Education and Training for Overseas Countries, 12 Lincoln's Inn Fields, London, W.C.2 (September 13).

SCIENTIFIC OFFICERS/SENIOR SCIENTIFIC OFFICERS (with an honours degree and postgraduate experience in entomology, botany or chemistry) AT THE TROPICAL STORED PRODUCTS CENTRE based at the Pest Infestation Laboratory, Slough, to spend part of the time overseas to undertake original investigations into problems associated with the handling and storage of foodstuffs in tropical climates, to evolve methods of improving quality and reducing losses, and to assist in the training of local personnel—The Research Department, Department of Technical Co-operation, Eland House, Stag Place, Victoria, London, S.W.1 (September 13).

ASSISTANT LECTURER or LECTURER IN SOCIAL PSYCHOLOGY—The Registrar, University College of Swansea, Singleton Park, Swansea (September 14).

SENIOR LECTURER IN CHEMICAL PATHOLOGY—The Secretary, St. Thomas's Hospital Medical School, London, S.E.1 (September 14).

RESEARCH ASSISTANT or RESEARCH FELLOW (with a university degree or equivalent qualification), for research on control of food intake in animals—The Secretary, Marischal College, The University, Aberdeen (September 14).

LECTURER IN BIOCHEMISTRY (Veterinary Biochemistry)—The Secretary of University Court, The University, Glasgow (September 15).

LECTURERS or ASSISTANT LECTURERS (2) IN THE DEPARTMENT OF GEOGRAPHY, University of Malaya—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Malaya and London, September 15).

ASSISTANT LIBRARIAN—The Secretary, The University, Aberdeen (September 16).

LECTURER (preferably candidate with medical qualifications registrable in the United Kingdom) IN PHARMACOLOGY—The Registrar, The University, Manchester 13 (September 16).

RESEARCH ASSISTANT (graduate) IN THE DEPARTMENT OF SOCIAL ANTHROPOLOGY AND SOCIOLOGY in the Faculty of Economic and Social Studies—The Registrar, The University, Manchester 13 (September 16).

SCIENTIFIC OFFICER or SENIOR SCIENTIFIC OFFICER (graduate of Ph.D. standing or equivalent experience) IN THE DEPARTMENT OF VIROLOGY, to specialize in serology of animal viruses—The Secretary, Institute for Research on Animal Diseases, Agricultural Research Council, Compton, near Newbury, Berkshire (September 16).

ASSISTANT LECTURER (preferably with a special interest in physical geography) IN GEOGRAPHY—The Secretary to the Trustees, Magee University, Londonderry, Northern Ireland (September 17).

TECHNICIAN (male, preferably with experience in mycology) AT RUAKURA ANIMAL RESEARCH STATION, Agriculture Department, New Zealand, for work concerned with the study of mycotoxicoses of grazing animals—The High Commissioner for New Zealand, New Zealand House, Haymarket, London, S.W.1, quoting Ref. B.13/2/22/2227 (September 18).

LECTURER IN ELECTRICAL THEORY AND MEASUREMENTS; a LECTURER IN ENGINEERING PHYSICS; and a LECTURER IN MATHEMATICS at Malta College of Arts, Science and Technology—The Council for Technical Education and Training for Overseas Countries, 12 Lincoln's Inn Fields, London, W.C.2 (September 20).

LECTURER or ASSISTANT LECTURER IN SOCIAL ANTHROPOLOGY at the University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (September 20).

RESEARCH FELLOW AT THE UNIVERSITY OF LONDON COMPUTER UNIT, to develop research in a branch of numerical analysis in collaboration with senior staff of the Unit—The Secretary, University of London Computer Unit, 44 Gordon Square, London, W.C.1 (September 20).

CHAIR OF ADULT EDUCATION to be held in association with the DIRECTORSHIP OF EXTRA-MURAL STUDIES—The Registrar, The University, Manchester 13 (September 23).

CURATOR (preferably with the N.D.H. or an equivalent qualification, and trained in and possessing a certificate from a botanic garden) OF THE BOTANIC GARDEN, Kwame Nkrumah University of Science and Technology, Kumasi, Ghana, for duties which will include a preliminary detailed survey, and planning and clearing the area—The Assistant Registrar, Kwame Nkrumah University of Science and Technology, 15 Gordon Square, London, W.C.1 (September 23).

LECTURER IN PATHOLOGY at Makerere University College, East Africa—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (September 25).

LECTURER IN MATHEMATICAL STATISTICS at the University of Sydney, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 27).

SENIOR LECTURERS/LECTURERS (preferably with research interests in the fields of invertebrate histology or embryology) IN ZOOLOGY AND COMPARATIVE PHYSIOLOGY at Monash University, Victoria, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (September 27).

CHAIR OF PSYCHOLOGY at the University of the Witwatersrand, Johannesburg, South Africa—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, September 30).

LECTURER (with some experience of hospital laboratory work, and preferably some teaching experience) IN THE DEPARTMENT OF CLINICAL CHEMISTRY—The Secretary, The University, Edinburgh (September 30).

MEDICAL LIBRARIAN (graduate with library qualifications and experience) for the Barr Smith Library, University of Adelaide, Adelaide, South Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, September 30).

PROFESSOR OF ANIMAL PHYSIOLOGY at the Waite Agricultural Research Institute, University of Adelaide, Adelaide, South Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Adelaide, September 30).

STANLEY ELMORE RESEARCH FELLOW IN EXTRACTION METALLURGY, including MINERAL PROCESSING, for work in the Department of Metallurgy of a University or similar Institution in the United Kingdom—The Secretary, The Institution of Mining and Metallurgy, 44 Portland Place, London, W.1 (September 30).

TEMPORARY LECTURER IN EDUCATIONAL PSYCHOLOGY—The Registrar, The University, Manchester 13 (September 30).

ASSISTANT LECTURER (honours graduate in physics and preferably an interest in electronics) IN THE DEPARTMENT OF PROSTHETICS, Turner Dental School, for duties mainly in research on electro-physiological measurements in the dental field—The Registrar, The University, Manchester 13 (October 2).

LECTURER IN MATHEMATICS at the University of Adelaide, Adelaide, South Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, October 4).

SENIOR LECTURER and a LECTURER IN APPLIED MATHEMATICS at the University of Sydney, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Australia, October 8).

LECTURER (preferably specialized in the psychology of education, including mental measurement) IN EDUCATION at the Institute of Education—The Registrar and Secretary, The University, Bristol (October 15).

SENIOR LECTURER or LECTURER IN PHYSICS at the University of Otago—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; or The Registrar, University of Otago, Dunedin, New Zealand (New Zealand and London, October 15).

ASSOCIATE PROFESSOR (with high academic qualifications in science, engineering or textile technology, and preferably research experience in the field of textile physics) IN TEXTILE TECHNOLOGY at the University of New South Wales, Australia—The Agent-General for New South Wales, 56–57 Strand, London, W.C.2; and the Appointments Section, The University of New South Wales, Box 1, Post Office, Kensington, N.S.W., Australia (October 31).

FOUNDATION CHAIR OF PSYCHOLOGY at Monash University, Melbourne, Australia—The Secretary, The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; or The Registrar, Monash University, P.O. Box 92, Clayton, Victoria, Australia (Australia and London, October 31).

READER or LECTURER (with a university degree in civil or agricultural engineering and with teaching and research experience preferably in soil and water engineering as related to agriculture or to conservation) IN AGRICULTURAL ENGINEERING at Lincoln College, University of Canterbury, New Zealand—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, October 31).

SENIOR LECTURER/LECTURER (with an honours degree in science or engineering and preferably with experience in the application of problems to digital computers) IN THE DIGITAL COMPUTING LABORATORY, School of Engineering Science, University of New South Wales—The Agent-General for New South Wales, 56 Strand, London, W.C.2; and The Appointments Section, University of New South Wales, Box 1, Post Office, Kensington, N.S.W., Australia (London and Australia, October 31).

AGRICULTURAL OFFICER (male, under 40, with a university degree in agriculture) IN THE DEPARTMENT OF AGRICULTURE, Bechuanaland Protectorate, for pasture research, vegetation surveys and soil conservation—The Director of Recruitment, Department of Technical Co-operation, Eland House, Stag Place, Victoria, London, S.W.1, quoting Ref. C.1/RC.213/11/04.

ASSISTANT (with special interests in inorganic or physical chemistry) IN THE DEPARTMENT OF CHEMISTRY—The Professor, Department of Chemistry, University College, Upper Merrion Street, Dublin 2, Republic of Ireland.

CHIEF LIBRARIAN (suitably qualified librarian, graduate of a university, and preferably some experience in a library of science or technology)—The Academic Registrar, Loughborough College of Technology, Loughborough, Leicestershire, quoting Ref. 24/G.

EXPERIENCED MEDICAL LABORATORY TECHNICIAN (or Senior Technician) FOR THE DEPARTMENT OF CHEMICAL PATHOLOGY—Prof. F. T. G. Prunty, William Dunn Laboratory, St. Thomas's Hospital Medical School, London, S.E.1.

FELLOW (preferably post-doctorate, with interest and ability in optics and electronics), to take part in the optical maser programme of the Department of Physics, with special emphasis on harmonic generation and non-linear optical effects—The Principal, Royal Holloway College (University of London), Englefield Green, Surrey.

NEUROCHEMIST (with a Ph.D. in biochemistry with postgraduate research experience in neurochemistry, or an interest therein), to participate in ongoing research programmes—The Director, Missouri Institute of Psychiatry, 5400 Arsenal Street, St. Louis, Missouri, U.S.A.

PHOTOGEOLOGIST (with a first- or good second-class honours degree in geology, about five years postgraduate experience in regional mapping and field geology, a good knowledge of photogeology, and preferably a knowledge of Spanish) with the Government of Peru, for the preparation of geological maps by means of photo-interpretation; some field work, and the training of locally recruited assistants—The Director of Recruitment, Department of Technical Co-operation, Eland House, Stag Place, Victoria, London, S.W.1, quoting Ref. RC.218/117/02.

PHYSICAL CHEMIST (with an interest in, and preferably experience of, surface chemistry), for studies of pigment particles and their behaviour in paint media; a PHYSICIST or PHYSICAL CHEMIST, for fundamental work on the rheology of pigment and polymer latex dispersions; and an ANALYTICAL CHEMIST, to take charge of a small laboratory for devising qualitative and quantitative techniques applicable to paint components, pigments, polymers, surface active agents, etc., and for analytical studies of paint blemishes and the causes of defects—The Director, Paint Research Station, Research Association of British Paint, Colour and Varnish Manufacturers, Waldegrave Road, Teddington, Middlesex.

RESEARCH ASSISTANT (graduate chemist or biochemist) IN THE ARTIFICIAL KIDNEY UNIT—The House Governor, London Hospital, Whitechapel, London, E.1.

RESEARCH ASSISTANT or TECHNICIAN (graduate or non-graduate), to work in the field of chemistry in relation to medicine—The Secretary, The Medical College of St. Bartholomew's Hospital, West Smithfield, London, E.C.1.

RESEARCH ASSISTANTS and FELLOWS, for full-time research on polymer problems—Head, National College of Rubber Technology, Holloway, London, N.7.

SENIOR LABORATORY TECHNICIAN (Grade II) (preferably with a knowledge of optical instruments and their maintenance) IN THE DEPARTMENT OF OPHTHALMIC OPTICS, to be responsible for the clinical laboratories in the Department—Head, Department of Ophthalmic Optics, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

SENIOR TECHNICIAN (preferably with a knowledge of glass-blowing) IN THE DEPARTMENT OF PHYSICS, to assist in a research programme on large-gap semiconductors—Dr. R. H. Tredgold, Department of Physics, University College of North Wales, Bangor, North Wales.

TECHNICIAN or GRADUATE ASSISTANT, for biochemical research on root growth and morphogenesis involving cell and organ culture—K. W. Fuller, Botany School, The University, Oxford.

SCIENTIFIC AND TECHNICAL AID FOR COMMONWEALTH COUNTRIES

IN replying for the Government in the debate on science in the House of Commons on July 15, the Secretary for Technical Co-operation, Mr. R. Carr, referred more especially to the role of Britain's scientific effort in the future of the Commonwealth. He pointed out that expenditure on overseas research, mainly in the Commonwealth, amounted in the current year to some £2 million. Of the figure of £2·3 million, given in a written answer by the Parliamentary Secretary for Science the following day, £2·16 million is through the Department of Technical Co-operation, but although Mr. Carr mentioned specifically a number of home-based units concerned with the problems of the developing countries, mainly in the Commonwealth, such as the Anti-Locust Research Centre, the Tropical Products Institute, the Tropical Divisions of the Road Research Station and the Building Research Station, the Tropical Store Products Centre and the Tropical Medicine Research Board, he gave no indication of the expenditure of any of these units.

All such information has been lacking since the publication of the report *Colonial Research* was terminated. Mr. Carr did, however, mention the very important work of the Land Use Section in the Directorate of Overseas Surveys, which was being strengthened further, and where soil scientists were doing very valuable scientific work in assisting the development of the natural resources of many of these countries. It was estimated that at present Britain was sending abroad to these countries more than 2,000 scientists, but part of her substantial contribution to scientific development in Commonwealth and in some other under-developed countries lay in the training of some 4,300 students of science at her universities and about 8,600 students at technical colleges.

Mr. Carr welcomed the reference of Sir Harry Legge-Bourke to the importance of this effort, but his speech did little to fill the gap left by the discontinuance of the reports on *Colonial Research*. By implication, however, his speech seemed to point to a continuing and increasing need for such a survey of overseas research, and this appears to have been in the background of recent debates on the report of the Colonial Development Corporation. The Corporation itself is not concerned with research, although there is a reference in the report to continued metallurgical research, partly at the Warren Spring Laboratory, with the view of developing an economic flotation process for a pyrochlore deposit, and the development projects for which the Corporation provides money could often not be possible apart from the results of earlier research. It also, however, brings in skilled management and skill in training local people as the managers of the future, and the benefits of its skilled management are not only reserved for the Corporation's own projects. As often as possible these benefits are placed at the disposal of small farmers in the countries in which the Corporation operates, and in this way the Corporation has not only done much to develop agriculture but has also contributed to the advances in understanding which make scientific and technical advance elsewhere possible.

When the Commonwealth Development Bill received a second reading in the House of Commons on June 19, there was considerable reference to the Corporation's report. In introducing the Bill, Mr. J. Tilney, the Under-Secretary of State for Commonwealth Relations, pointed out that the Corporation's operating surplus had risen from £1,869,000 in 1959 to £4,361,000 in 1962, when the profit was £1·6 million; since 1952 only £250,000 had been lost, although by that date £12 million had been lost out of the then investment of £21 million. The total investment now approaches £100 million and is handled by a head office staff of 157 and a regional staff of 78, compared with a head office staff alone at the end of 1951 of 325. In 1962, the Corporation's investment in manufacturing and processing enterprises alone was associated with a turnover of £38 million, of which goods worth £23 million were exported from the territories concerned, and these activities last year generated more than £7 million of British exports. Mr. Tilney emphasized that on the successful establishment of a project the Corporation was ready to dispose of its investment at a satisfactory price, particularly to buyers resident in the country where the project was located, and the proceeds of such a sale were available for use in the development of some other project.

Mr. Tilney explained that the Bill amended the Overseas Resources Development Act 1959 and the Colonial Development and Welfare Act 1959 so as to put back into the sphere of activity of the Corporation, now to be renamed the Commonwealth Development Corporation, all Commonwealth territories which were within its scope when it was set up in 1948. The Corporation would, however, be instructed to seek the prior approval of the Secretary of State for Commonwealth Relations before starting operations in an independent country and that approval would be given only with the agreement of the Government of that country. The Corporation would still be excluded from India, Ceylon and Pakistan, and while the late Mr. John Strachey strongly challenged this in the debate, holding that the Corporation should not be stopped from initiating a project anywhere in South-east Asia if it wished, the Under-Secretary of State for the Colonies, Mr. N. Fisher, maintained that the Corporation could already exercise advisory functions in those countries. The Government view that to do more would seriously disturb the balance of the Corporation's activities was maintained in the subsequent debates at the Committee stage and in the House of Lords.

Mr. Tilney added that there was no intention of raising the present limit of £130 million in the amount the Corporation could borrow from the Treasury, and, turning to the colonial development and welfare provisions of the Bill, he said that the Bill extends the period for making and approving such schemes from March 31, 1964, to March 31, 1966, increasing from £315 million to £340 million the amount which could be spent on schemes under Section 1 of the Act. Since by March 31, 1963, about £43·5 million was unexpended, about £68·5 million would be available for the three years 1963–66. While previously research and technical assistance had been provided under the Colonial Development and Welfare Acts, this expenditure was now financed by the Depart-

ment for Technical Co-operation, but the change did not imply any decrease in the amount of research carried for the benefit of the colonial territories. When the Bill was introduced into the House of Lords on July 16, the Minister of State for Colonial Affairs, the Marquess of Lansdowne, repeated that the change did not mean that any less importance was attached to research activities or technical assistance.

While the Bill was generally welcomed in the House of Commons and some warm tributes were paid to the work of the Colonial Development Corporation, the chief criticism was in respect of the exclusion of the Corporation from India, Ceylon and Pakistan and on the limitation on its Treasury borrowing. Mr. T. Dalyell made a useful suggestion that the Corporation could assist in supplying some printing and paper-making apparatus which would enable the developing areas to cope with their critical shortage of paper, writing paper and text-books—a suggestion which Mr. Fisher promised to note particularly—but Mr. P. Walker challenged the Bill as failing to meet the need of potential investment in the Commonwealth. Mr. G. M. Thomson, directing attention to the anomalous position of the Corporation with reference to the Colonial Office, the Commonwealth Relations Office and the Department of Technical Co-operation, thought that the Corporation should now come under the last and that it might usefully play some part in the administration of Colonial Development and Welfare funds.

Criticism of the placing of the Colonial Development Corporation under the Commonwealth Relations Office was again voiced in the House of Lords on July 16 when the Earl of Listowel again advocated the merging of the Colonial Office and the Commonwealth Relations Office and urged the appointment of a new 'minister for overseas development' to watch the increasing importance of this function of Government. Such a Minister, with a seat in the Cabinet and responsible for the whole of Britain's overseas aid, would be responsible for all non-military Government expenditure in developing countries. Besides his concern with an adequate share of Government expenditure and as the spokesman of British aid, he would determine priorities relative to the limited amount of capital and technical aid available and would co-ordinate both money and technical skill. He would also ensure that representatives of recipient countries and of international bodies giving aid were fittingly received.

The Bill was generally welcomed in the House of Lords also, but the Marquess of Lansdowne was very guarded concerning Lord Listowel's suggestion of a single minister for overseas development. Neither in the Lords nor in the Commons, however, was there any further specific reference to research and it would seem that a further opportunity has been missed of directing attention to a conspicuous omission over the past two years or more. Despite the importance of overseas research, both in relation to economic development and to educational development, and the alarm in particular quarters over the threatened closure of important research institutes, Britain is not being given the information on which to base a realistic opinion as to the scale and disposition of her effort in that field, or as to whether the existing arrangements are appropriate and efficient. This is a matter to which the Department of Technical Co-operation should be giving urgent and increased attention with the full support of all scientists working in this field.

A GREAT MATHEMATICIAN

The Mathematical Works of J. H. C. Whitehead

Edited by I. M. James. Vol. 1: Differential Geometry. Pp. xxxiii+361. Vol. 2: 'Complexes and Manifolds', Pp. xiii+435. Vol. 3 : 'Homotopy Theory', Pp. xiii+451. Vol. 4: 'Algebraic and Classical Topology', Pp. xiii+347. (Oxford, London, New York and Paris: Pergamon Press, 1962.) 84*s*. per volume; £15 per set.

THE question whether the publication of the collected works of a mathematician is justified is one on which there can be more than one opinion. It can be argued that the labour involved in editing the papers and the cost of the collected edition are scarcely justified in these days when almost everyone has access to a good library of mathematical journals, and there are many efficient reference books. This is indeed a valid argument if the publication is simply an act of piety; and it is even more true if most of the author's papers, though of importance at the time when they were written, are of ephemeral interest. But there are cases when the publication of the collected works of a mathematician can be a real service to the mathematical community; as, for example, when the mathematician in question has been at the centre of one or more of the major developments of his time. Then it can be of great value to those who come after him to see the subject unfolding itself, and to re-capture the spirit behind the original development.

The publication of the collected papers of Henry Whitehead is fully justified. When Whitehead first began his work on topology, he and Prof. M. H. A. Newman were the only two British mathematicians who were making any significant contribution to the subject. While Prof. Newman, though he has maintained his interest in topology and has made significant contributions to it, has extended his interest in mathematics beyond what is strictly topological, Whitehead devoted all his energies to tackling major problems in topology, and so establishing himself as a world figure in this field. Many of Whitehead's contributions are fundamental in topology, and some of his methods are still the most powerful available: thus, for example, the proof of the generalized Poincaré hypothesis given by Dr. Stalling just after Whitehead's death is based on the foundations laid by him in 1940. There is now a large and distinguished British school of topology; many of its members owe everything to Whitehead, and all owe him a great deal. To all of them his collected works will be invaluable. Whether they can all afford to purchase the four volumes is perhaps a doubtful question, but for mathematical libraries they are 'a must'.

Dr. James, the editor, is to be congratulated on the speed with which he has brought the volumes out; the value of the collected works would have been greatly reduced had we had to wait for them as long as we have had to wait for the collected works of some others. In order to achieve this, Dr. James has had to work to a very simple plan which has resulted in some loss of elegance. The papers are fairly easily classified. In the main, Whitehead's work on any particular topic was done at one time, and the order is broadly, though not completely chronological. Other publications, such as the Cambridge Tract on the *Foundations of Differential Geometry* (written jointly with Veblen), and the very informative biographical memoir of Elie Cartan, written for the Royal Society are easily fitted into their proper place. The first volume contains all Whitehead's writings on differential geometry and Lie groups, and covers the first phase of his mathematical activity; the second volume deals with his work on complexes and manifolds, and contains some of the papers which established him as a world figure; the third volume contains the papers in which Whitehead made his massive contribution to homotopy theory and the final volume deals with fibre spaces and the

Spanier–Whitehead *S*-theory, and ends with his final papers on classical topology. Only a limited amount of editing has been done; a very few corrections have been made, and the headings of papers have been reduced to uniform style. A small criticism is that the papers are not numbered, and the original place of publication is not given with the papers; this slightly complicates the task of following up cross-references. The reproduction has been by a photographic process from reprints; the result is at first a little disconcerting, due to the varieties of type used by the different journals in which the papers originally appeared.

Each volume contains a complete bibliography of Whitehead's works, and the table of contents of all four volumes, as well as an extremely good portrait (the same in each volume). In addition, the first volume contains a delightful personal memoir by Prof. M. H. A. Newman and Mrs. Whitehead, and a critical appreciation of Whitehead's contributions to mathematics by Prof. John Milnor of Princeton University.

Prof. Milnor's appreciation is so just, and so illuminating, that it would be an act of supererogation to attempt another here. Both this, and the personal memoir, recall vividly to my mind my own relations with Whitehead. I do not think I ever met anyone who so obviously enjoyed mathematics. I was very seldom in his company when the conversation did not turn, sooner or later, to mathematics, not because he had no other subjects to talk about, or because he wanted to talk of what he himself was doing. He usually talked about the mathematics that interested his audience, and if he could find a relation between this and what he himself was doing, so much the better. But it was no monologue; everyone was drawn in and enjoyed the discussion, usually much more than he normally enjoyed talking shop. Whitehead's enthusiasm was infectious, and this was one of the reasons why his lectures were so stimulating. I never heard him deliver a formal course of lectures; but on many occasions I have been present when he gave a talk to a mathematical society, or a seminar, or a students' club—and he was most generous in giving such talks. Viewing them from the narrow standpoint of lecturing technique, I suppose one would say they were not good lectures: he often gave the impression of feeling his way while he was speaking, so that at first one might think that the acknowledged expert did not know much about his own subject, but he carried his audience with him, and aroused their interest, and at the end one was surprised to realize how much had been achieved. His style was most informal: he usually lectured with a piece of chalk in one hand and a cigarette in the other, and not infrequently there was an interruption when he got their functions interchanged. But for ability to provoke enthusiasm, he had few equals.

Whitehead was that *rara avis*, a mathematician who grew in stature as he grew older. His first work, in differential geometry, was done under the influence of Veblen, and his early work in topology showed the influence of J. W. Alexander and Lefschetz. In this, while he achieved some valuable results, and seemed, in a way, to be moving towards some of the great achievements of later years, he still seemed to be groping for something to give him a real chance. The big break came at the International Congress of Mathematicians held in Oslo in 1936, when discussions held with other mathematicians present stimulated his interest in the problems of homotopy. His achievements in this field came much later, but from then on his work seemed to have more direction. He was just getting into his stride when the War interrupted his career.

He was forty when the War ended, and the task of getting back into the stream would have daunted many of his age. But he never faltered, and he took up where he had left off, and when, in 1947, he became Waynflete professor at the University of Oxford, he was ready to take full advantage of the opportunities which the appointment offered. From then, he went on from strength to strength, and although he was fifty-five when he died there was never the slightest sign of any decline in his powers. The frequent visits that he paid to Princeton had, I think, much to do with his success. His easy manner with all with whom he came in contact enabled him quickly to absorb the latest trends, and refreshed by these visits he returned to Oxford to stimulate the growing school of topologists there, which he left without a rival in the country. Every topologist of any standing has at some time been either his pupil or his colleague, and he had an unrivalled gift of getting the best out of anyone with whom he came in contact. The number of distinguished pupils who freely acknowledge what they owe to Whitehead is an even more fitting memorial to him than these four excellent volumes of his mathematical works.

W. V. D. HODGE

COMMUNICATIONS SATELLITES

Communications Satellites

Proceedings of a Symposium held in London, 12 May 1961, organized by the British Interplanetary Society. Advisory Editor: L. J. Carter. Pp. ix + 202. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1962.) 42*s*.

WITHIN the last two years there have been held, in Great Britain, three conferences concerned with the use of satellites for world-wide radio-telephone and television communications. The first of these was organized by the British Interplanetary Society in London in May 1961, the second by the British Institution of Radio Engineers at Oxford in July 1961 and the most recent by the Institution of Electrical Engineers in London in November 1962. The great interest in the subject arises because satellites appear to provide the only means of bringing about a major expansion in communications capability to meet global needs. Communications satellites cannot, however, be a success unless use is made of the very latest scientific knowledge in a number of different fields. These include the design of radio receivers with the lowest possible internal noise, the design of very-high-power transmitter valves, the design of electronic circuits which are insensitive to radiations occurring in space and the development of communication—theories on how best to modulate radio waves in order to transmit the maximum number of telephone channels with given equipment.

This book contains eight collected papers which were read at the first of the three symposia. Since then, much has happened. The *Telstar* and *Relay* satellites have been successfully launched, and organizations such as the General Post Office have obtained a wealth of practical experience on the use of satellites and the associated ground terminal equipment for television and other communications. The book, therefore, cannot be regarded as completely up to date. In addition, the papers contain relatively little on the various problems of designing low-noise receivers, large aerials and transmitters for the ground terminals and little on the detailed design of relay equipment for satellites.

In spite of these limitations, however, the book does contain some very useful theoretical papers on the general design of communication systems involving satellites. Such features as the optimum shape of orbit, height of satellite and operating frequency are considered in several papers and it becomes clear that to be commercially successful the satellites must be active repeaters, not passive reflectors such as the *Echo* balloon, and that they should be controlled in their relative positions and attitude with respect to the Earth. One particularly difficult matter to resolve is the optimum type of radio

modulation to use. This problem, which has to be considered in the light of the required services and satellite technology, is dealt with in two papers, and the conclusion drawn is that a form of pulse code modulation should be used. In contrast, both the *Telstar* and *Relay* systems actually use wideband frequency modulation. A minor point is that one paper (p. 177, Fig. 31), which discusses the overall cost of satellite systems, appears to treat the ground terminals and the satellites as separate items. Thus as the satellite height is increased, the satellite cost increases rapidly while the terminal cost is shown at a constant figure. Perhaps with high altitude orbits it would have been preferable to consider smaller satellites, in order to minimize launching costs, and to accept larger ground terminals than would be needed in the low altitude case. T. W. G. Dawson

RADIO WAVE PROPAGATION

Monograph on Radio-Wave Propagation in the Troposphere

Proceedings of Commission II on Radio and Troposphere during the XIIIth General Assembly of URSI, London, September 1961. Edited by J. A. Saxton. Pp. viii+200. (Amsterdam and New York: Elsevier Publishing Company, 1962.) 48*s*.

Monograph on Ionospheric Radio

XIIIth General Assembly of URSI, London, September 1960. Edited by W. J. G. Beynon. Pp. vi+264. (Amsterdam and New York: Elsevier Publishing Company, 1962.) 65*s*.

Monograph on Radio Noise of Terrestrial Origin

XIIIth General Assembly of URSI, London, 1960. Edited by F. Horner. Pp. vii+202. (Amsterdam and New York: Elsevier Publishing Company, 1962.) 48*s*.

Space Radio Communication

A Symposium held under the Auspices of the International Scientific Radio Union in Paris in September 1961. Edited by G. M. Brown. Pp. xii+630. (Amsterdam and New York: Elsevier Publishing Company, 1962.) 140*s*.

The Measurement of Characteristics of Terrestrial Radio Noise

(URSI Special Report No. 7.) Pp. vii+58. (Amsterdam: Elsevier Publishing Company, 1962.) 25*s*.

Radio Wave Propagation and the Ionosphere

By Ya. K. Al'pert. Authorized translation from the Russian. Pp. x+394. (New York: Consultants Bureau, 1963.) 22.50 dollars.

THE first five volumes listed here are reports from the Union Radio Scientific Internationale (URSI), one of the Unions of the International Council of Scientific Unions. Three are reports of the meetings of separate Commissions at the thirteenth General Assembly held in London in 1960, one is a report of a special symposium on "Satellite Communications" held in Paris in 1961, and one belongs to a series of special reports prepared by URSI, from time to time, on radio topics of particular interest.

Radio-Wave Propagation in the Troposphere is a report of the 1960 meetings of Commission II which were devoted to the subjects of experimental data on tropospheric propagation, physical characteristics of the troposphere, theories of tropospheric propagation, and radio-meteorology and climatology. It contains twelve papers on these subjects.

Ionospheric Radio is a report of the meetings of Commission III. It contains sixteen papers dealing with the electron-density/height profiles $N(h)$, $F2$ region ionization, sporadic E ionization, rocket and satellite data, very-low-frequency emissions and hydromagnetic waves, aurorae, ionospheric scattering, and ionospheric drifts.

Radio Noise of Terrestrial Origin presents edited reports of the meetings of Commission IV and covers sources of noise in lightning, properties of natural noise, International Geophysical Year whistler data, very-low-frequency emissions and hydromagnetic waves, whistler theory, the exosphere, man-made noise, very-low-frequency propagation, together with ten invited papers on some of these subjects.

Each of the volumes contains an edited account of the discussions which took place at the meetings. The accounts for Commissions II and III are given more or less verbatim.

The appearance of these three volumes prompts one to ask how far publication of the proceedings of meetings of this kind is justifiable, or valuable. In this context it must be remembered that the more formal *Proceedings* of the General Assembly are fully reported in the publications of URSI itself, the volumes here reviewed are concerned only with scientific aspects of the proceedings. They might serve one or more of the following purposes: (*a*) to provide an account, for historical reasons, of what was said at the meetings; (*b*) to provide good critical surveys of the subject; (*c*) to give summarized, but non-critical, accounts of work done by different groups or countries; (*d*) to present new results. It is thus worth asking how far these purposes are accomplished and how far their accomplishment is desirable.

The basic subject-matter of the three volumes is not new, it has been studied for several years, and there is inevitably, in all the papers, much that is well known. Where there is something new it has to be sought out from among the older material. For meetings of this kind it is seldom that authors have time, or inclination, to prepare really penetrating new critical surveys, and the 1960 General Assembly was no exception. The most useful are probably those by Briggs on ionospheric drifts and by Storey on whistlers. The other survey papers are more accurately described as summaries, often of work in one particular country. The 'edited discussions' are tedious to read, with important and trivial remarks intermingled; one would scarcely expect to look there for considered opinions.

Although I myself appreciate and admire the large amount of effort and time that has been put, by authors and editors, into the production of these volumes, I believe that it was mistaken policy to publish them, and that they represent an unfortunate waste of time for the writers, editors, and (perhaps even more important) for the readers. If they contained a really good critical review, or original paper, then it should, in my opinion, have been published in the usual way in a recognized scientific journal. The only purpose which the volumes achieve satisfactorily is to provide an account, for historical reasons, of what was discussed at the meetings; but a printed book is not required for that purpose. It is to be hoped that URSI will consider carefully its policy for publishing the results of the next General Assembly to be held in Tokyo in September this year.

Space Radio Communication is the report of a symposium organized by URSI. It contains 38 papers divided under the headings "Introduction", "Launching, Altitude Control and Tracking of Satellites", "Frequency Allocation, Interference and Propagation Problems", "Satellite Equipment", "Ground Equipment", "Modulation Systems", "Specific Communication Systems", and "Miscellaneous Aspects". Because the subject is a very new one the report is not open to the foregoing criticisms. There is little repetition of well-known material and most of the papers present what to many readers will be new and interesting ideas. The book as a whole provides a stimulating introduction to the subject. As a minor

criticism, it might be asked whether there was any value in including the three introductory formal addresses.

The Measurements of the Characteristics of Terrestrial Radio Noise was prepared by a working party set up at the eleventh General Assembly to discuss the problem of measuring and specifying the characteristics of radio noise in a manner useful to the design of a communication system. It describes how the noise is received on narrow-band receivers tuned to different parts of the radio spectrum and observations are made on the amplitude distribution and the time variations of the envelope of the output E.M.F. The different methods of measuring are discussed and recommendations are made for observations on a world-wide scale. The question of which characteristics of the noise are important for different types of communication is discussed. The problems involved are complicated, and it is perhaps not surprising that no very clear conclusions are reached.

The well-known book on *The Propagation of Radio Waves* by Al'pert, Ginzburg and Feinberg was published in 1953 and when the time came for re-writing it was split into three parts, each written by one of the authors. Al'pert wrote *Radio Wave Propagation and the Ionosphere*, which was published in Moscow in 1960, and it now appears in an authorized translation published in the United States. The book is divided into two parts, "The Ionosphere", and "Propagation of Radio Wave of Different Frequencies". The first part deals with the structure of the ionosphere, the theory of its formation, its regular and irregular variations, and the collision frequency of electrons. The second part deals, in succession, with ground waves, long, medium, short, ultra-short and micro-waves. The theory of tropospheric propagation is dealt with when the shorter waves are discussed. There is a bibliography of 243 key papers, a large portion of them in languages other than Russian. It is noticeable that the text contains a large proportion of diagrams copied direct from well-known papers in other languages. The book as a whole presents a clear account of the subject, somewhat out of date in some particulars, but of considerable interest when it deals with the author's own work.

J. A. RATCLIFFE

GEOLOGY OF IRELAND

Historical Geology of Ireland

By Prof. J. K. Charlesworth. Pp. xxiii+565 (140 illustrations). (Edinburgh and London: Oliver and Boyd, Ltd., 1963.) 84*s*.

THE aim of this book is to produce an advanced and comprehensive account of Ireland's geology. This is a major undertaking and one which has not really been attempted until now, for Cole and Hallissey's small volume of forty years ago was scarcely an advanced treatise. Clearly, no Irish geologist is more fitted to undertake this work than the illustrious author who, as head of the Department of Geology in the Queen's University of Belfast for more than thirty years, has vigorously worked in his special field of Irish glacial geology, and in many other topics as well. His earlier work—an elementary study of Irish geology in the nature of a school's or general reader's reference book—will have served as a preliminary to the present volume.

This book fully merits the title 'comprehensive'. In its bibliography of more than 750 references the reviewer could note only one or two very minor omissions. Nearly all the items receive some consideration in the text. In addition, it is fully up to date. In fact, several of the works to which the author has had access have not yet appeared in print. Such has been the development of Irish geology that a comparable work, if written a decade ago, could not have had much more than half the present coverage.

But the day must be at hand when an advanced work by a single author, covering the whole field of any science, is a practical impossibility. One wonders if—relative to the present work, for example—the advantages of a uniform style, treatment, and outlook can really counterbalance the difficulty in acquiring a first-hand, specialist, acquaintance with every actively developing field in geology.

The book achieves a great deal: its limitations are those which are to-day inherent in a treatment of this sort. It is, strictly speaking, a compilation. As such, it is a thorough one and an invaluable source of Irish geological knowledge. It treats all the major works on Ireland's geology equitably and carefully, the coverage is sometimes uneven, and for areas not recently investigated may be decidedly thin. The enumeration of local rock successions and rock groups *in extenso* can make for difficult reading, and in the accounts there is seldom any distribution of emphasis to help the general reader. Correlations of rock groups are often taken from old works and may not please the modern specialist. One would often wish for something of the more lively background of rock genesis and structural evolution. In particular, one misses any attempt to relate the country's geology to the broader setting of that of north-western Europe.

But, all in all, it is a most important and carefully compiled work, and will hold the field as a standard reference for many a day. It is a book designed, not for easy reading, but as a source in which the advanced student or professional worker can obtain accurate information on any aspect of Irish geology. In this way it fulfils a major requirement in Irish science, and should in later editions acquire the status of a great scientific work. This reviewer would wish, in particular, to see co-operation of the author and specialist workers achieving comprehensive syntheses of the geology treated in each chapter of the work, with the country's setting clearly depicted in relation to the general European background. Clearly, too, the work demands a series of specially drawn illustrations, laborious and costly though their preparation may be. The present figures are adequate in number and scope, but they are an irregular hotch-potch culled from original papers over the past sixty years or more. Each one was designed for a particular purpose, and it is seldom really suitable for the present work. Sometimes inaccuracy is thus introduced. Fig. 56, for example, though it has appeared in both the authors' works, has not yet resolved the confusion between reef-knolls and volcanic rocks. On a technical point, more attention might be given to misprints, which are common in the case of technical terms and place-names. To the expert they are no more than blemishes in a finely produced book, but the tyro may find them confusing.

J. C. BRINDLEY

GEOLOGY OF A NATURE RESERVE

The Geology of Moor House

A National Nature Reserve in North-East Westmorland. By Dr. G. A. L. Johnson. With contributions by Dr. K. C. Dunham. (Monographs of the Nature Conservancy, No. 2). Pp. xviii+182+14 plates. (London: H.M. Stationery Office, 1963.) 55*s*. net.

THIS volume follows the first monograph on *The Plant Communities of the Scottish Highlands* and is in sharp contrast in scope.

The Moor House National Nature Reserve comprises some 10,000 acres of high-lying, remote mountain and moorland, straddling the Pennine Watershed a little south of Cross Fell. This comprises a comprehensive account of the solid geology and the vitally important superficial modifications of glacial and post-glacial times and includes a detailed account of the soils.

The Conservancy wisely welcomed the proffered co-operation of the Geology Department of the University of Durham, and a detailed survey of the solid rock, drift deposits and soils was carried out by Dr. G. A. L. Johnson under Prof. K. C. Dunham's direction.

Detailed stratigraphy and palæontology of the Carboniferous rocks and associated Older Palæozoic and younger igneous intrusions occupy rather more than one half of the volume. There is also a new geological map in colour, on a scale of three inches to one mile. There are minor changes in correlation in the classification of the North Pennine Carboniferous. The retention of the 'Upper Limestone Group' formational name for the Namurian strata present and the elimination of the term 'Carboniferous Limestone Series' may be noted.

Clay mineralogy investigations, mainly by differential thermal analysis, have confirmed the dominance of illite in marine sediments and the restriction of the kandite clays to the deltaic and terrestrial part of the prevalent rhythmic or cyclothermic depositional pattern. The differential thermal analysis graphs and the commentary are a valuable contribution.

Prof. Dunham's two chapters deal succinctly with geological structure and mineral deposits. The latter comprise the important lead and barytes-bearing Dun Fell and Henrake Vein Complex. A short chapter on geomorphological setting could have been included here with advantage.

The last third of the book, which deals fully with the Quaternary, has perhaps the widest appeal. It is based on a detailed survey, the results of which are embodied in a new soil map. Glacial boulder clay of local origin is widespread beneath the peat. The great importance of solifluction processes, particularly in the distribution of mineral soils, is emphasized. Sandstone blockfield type of accumulation often overlies boulder clay, and stone polygon structures beneath the peat testify to the fossil character of much of these movements; but at these high altitudes solifluction processes are still active.

Laboratory investigations of soils have indicated the increasing importance of mixed-layer chlorite–illite at the expense of illite in the progressive conversion of bedrock to glacial drift, solifluxion deposited mineral soils. Typical profiles are given for a range of gleys, podsols, brown earths and peat soils and their variations according to physical environment described. Detailed profiles of thick bog and blanket peats are accompanied by full pollen diagrams which confirm and amplify the results of earlier workers.

The change from maximum spread and growth of the peat in Atlantic times to pronounced erosion is linked with the onset of cold, wet conditions of the Sub-Atlantic phase following the warm, dry, Sub-Boreal phase. In view of the widespread association elsewhere in peat stratigraphy of erosion intervals during warm dry phases, is it not perhaps more likely that localized drying out and cessation of peat growth were associated with weathering and local erosion in the Sub-Boreal ?

Subsurface channelling and surface collapse in peat bogs is said to be exactly paralleled with the erosion cycle in limestone country—surely this is heightening of what Is an interesting analogy in which solution and joint control factors in limestone imply very different processes. But the peat process is worthy of further study.

Generally topics are introduced at an elementary level as befits a work with a wide range of potential readers. Some stricter editing could have eliminated a number of minor repetitions. There are a good bibliography and index. The whole volume is an admirable beginning for a series of geological monographs for nature reserves which set the fundamental background for developing biological studies. The author and the Nature Conservancy are to be congratulated on a well-produced, clearly illustrated and scholarly contribution to knowledge.

S. E. Hollingworth

ZOOLOGICAL MICROPALÆONTOLOGY

Principles of Zoological Microplæontology

Vol. 1. By Dr. Vladimir Pokorny. Edited by John W. Neale. Translated by K. A. Allen. (International Series of Monographs on Earth Sciences, Vol. 10). Pp. xiv+652. (London and New York: Pergamon Press, 1963.) 84*s*. net.

THIS long-awaited English translation is a valuable and welcome contribution to the basic literature available to micropalæontologists.

The book, originally compiled from the author's lectures for students at the University of Prague, was first published in Czech in 1954, and afterwards published as a revised and expanded German edition in 1956. The new English edition, which is a direct translation from the German, does not contain any significant additional subject-matter.

Principles of Zoological Micropalæontology is intended as a hand-book of instruction for the advanced student or research worker, and as a reference work for the commercial micropalæontologist. It deals with seven different groups of microfossils, but principally with the Foraminifera. More than half out of a total of five hundred and nineteen pages, exclusive of the bibliographies, etc., are devoted to this order of the protozoa. Three short introductory chapters deal with micropalæontological definitions, methods, techniques, and microstratigraphical principles ; these are interesting and useful but general in approach. In six brief chapters the Radiolaria, Thecamoebae, Tintinnina, Chitinozoa, Hystrichospheres and certain problematic microfossils are discussed. The principal facts relating to the morphology, biology, structure and ecology of each group are given together with an outline of the classification. There is also a short account of the geological distribution and the history of research on each group of organisms.

As a preface to the taxonomy of the Foraminifera the author discusses the principles underlying a natural system of classification for the order. This section is Pokorny's main philosophical contribution, and consists of a critical appraisal of contemporary Russian thought on evolution, and its application to the classification of the Foraminifera.

It is strange to find that the author in his interesting historical survey of foraminiferal research does not refer to the systems of classification proposed by such workers as Cushman and Glaessner, although his own classification is a natural development of the scheme proposed by Glaessner in his *Principles of Micropalæontology* (1945). Pokorny recognizes nine superfamilies, compared with Glaessner's seven, and he subdivides these into sixty families and forty-two subfamilies. The generic descriptions are usually very brief, and most are illustrated by line drawings or photographs. In some instances, particularly among the larger Foraminifera, these are completely inadequate; the family Miogypsinidae is a case in point. There is only one line drawing of a schematic equatorial section for the genus *Miogypsina*, and the other genera in the family are not illustrated. Perhaps the most serious criticism which can be levelled against a book of this kind is that many well-known and quite important genera, for example, *Kathina*, *Brotzenia*, *Cycloloculina*, *Nubeculina*, *Praerhapydionina* and *Sherbornina*, to name only some, have been omitted, while other genera of doubtful validity, for example, *Epistomina*, have been included. It appears that the commonly occurring European genera are well represented, but the author's treatment of those found elsewhere is less adequate.

The section dealing with the geological distribution of the Foraminifera is useful since the records of the range of the Palæozoic genera have been brought up to date and recent Russian work has been included. A short glossary of terms in English, French, German and Russian

completes the chapter on the Foraminifera. This should be useful to research workers dealing with original papers, but the transliteration of the Russian terms mean that it has lost some of its value. The other microfossils are discussed in a much less exhaustive manner than the Foraminifera, for example, only the orders, suborders and superfamilies of the Radiolaria are described, and only the Tintinnina and the Hystrichospheres are treated generically.

The complete bibliography of seventy-five pages is generally adequate up to 1956, but since the more recent literature is not included, the book is already seven years out of date. One strong point, however, in favour of the work is the inclusion of numerous Russian references in the bibliography. These are not to be found in any comparable text-book in English.

In comparison with the German edition, the present edition is rather poorly bound and more bulky, with an extra seventy-two pages; typographical errors are frequent and there is a loss of quality in the half-tone illustrations. In spite of the fact that there are defects and omissions the book reveals the author's careful attention to his principal object, which is the lucid presentation of a large amount of factual material.

D. D. Bayliss

MEDICAL BIOCHEMISTRY

Medizinische Biochemie

Lehrbuch für Studierende und Ärzte. Von Dr. S. M. Rapoport. Pp. xvi + 992. (Berlin: Veb Verlag Volk und Gesundheit, 1962.) 53 D.M.

THE author of this book is a professor in the Humboldt University of Berlin and is also the director of the Institute of Physiological Chemistry of the Faculty of Medicine. The publication, which is from East Germany, is well printed on good paper and is written in German. The contents of the publication shows meticulous care in preparation and there is a liberal supply of tables, graphs, illustrations and photographs.

The book is divided into four sections. The first section, consisting of 200 pages, is concerned with the dynamic biochemistry of the living organism. As an introduction, the significance of physiological chemistry is discussed and a short historical background is included. The remainder of the section deals with physicochemical problems, the function of water and ions in the organism, proteins, enzymes and the chemistry of the cell. This section contains numerous diagrams, graphs, tables, illustrations and photographs.

In the second section, 336 pages are devoted to the intermediate metabolism of carbohydrates, lipids, steroids, amino-acids and proteins, nucleic acids, and porphyrins and hæm compounds. The subject-matter is particularly well illustrated with diagrams, graphs, etc. Reference is made to disease in those cases in which a disorder of metabolism is involved. In the third section, 246 pages are devoted to functional biochemistry. Salt and water metabolism and the influence of hormones are discussed. There are sub-sections on acid-base equilibrium, the composition of blood and the biochemistry of renal and liver functions. The biochemistry of muscle, connective and nervous tissues is discussed. There are also sub-sections on the biochemistry of reproduction, lactation and immunochemistry. The section is well illustrated with diagrams, tables, etc. Reference is made to disease in discussion of some of the biochemical phenomena.

The fourth section deals with problems very largely concerned with nutrition such as mineral metabolism, for example, iron, calcium and phosphorus. There is a large sub-section devoted to the vitamins. The section also includes a list of journals and review books that are related to the subject and are published throughout the world. Russian periodicals are included in this list. It is unfortunate that *Clinical Chemistry*, *Clinica Chimica Acta* and *Recent Advances in Clinical Chemistry* are not included in this very comprehensive list. The section concludes with the syllabus of the subject as taught in the author's department. Practical exercises are not included but there are frequent references to and descriptions of specialized techniques such as used in the examination of the structure of proteins, etc. Each sub-section is followed by a series of questions which the reader at his discretion may attempt to answer. The applications of biochemistry to the study of disease, usually considered under the headings of clinical chemistry or chemical pathology, have not been discussed except in the explanation of certain biochemical phenomena.

The subject-matter is rather more than required of the student of medicine in Britain and is probably more suitable for those reading for a degree in biochemistry with a bias towards medicine. The book would be of great value to the student of biochemistry conversant with the German language or one wishing to become conversant not only with biochemistry but also with the German language.

S. L. Tompsett

BEHAVIOUR OF THE RAT

A Study in Behaviour

Principles of Ethology and Behavioural Physiology, Displayed mainly in the Rat. By S. A. Barnett. Pp. xvi + 288 + 14 plates. (London: Methuen and Co., Ltd., 1963.) 45*s*.

IN this book Dr. Barnett restricts himself almost entirely to the behaviour of his favourite experimental animal, the rat. It is very useful to have such a study since the rat is by far the commonest item of the fauna of the modern biological laboratory—particularly that of the physiologist and psychologist. But, so far as wider objectives are concerned, the choice of the rat is unfortunate. Although the annual output of papers on this animal, or on some parts of it, is quite overwhelming, it does not provide in itself very convenient material for setting forth the principles of ethology. This is partly because it shares with many mammals the disadvantage of possessing relatively little of the fixed, species-specific, unlearned (instinctive) type of behaviour. Moreover, the author is so careful not to commit himself to any particular series of concepts or definitions of ethology that he tends at times to be confused by his own caution; so one begins to doubt what it is, in a given set of observations or experiments, that he finds interesting or important, and why. Of particular interest are those fields to which the author himself has most contributed, namely the behaviour of the wild Norway rat, the exploratory learning of rats and its psychological significance, and studies on the physiology of the stress which results when a rat is caged in the territory of a rival. Indeed, apparently perfectly healthy rats may die of shock in such circumstances; this lethal shock involves a whole series of neural and endocrine changes associated particularly with the sudden and severe drain on the secretion of the adrenal glands. As to exploratory behaviour, this is a phenomenon found very widely in the animal kingdom, and Barnett has made the particularly important point that exploratory learning in rats, as in the cautious sniffing and exploration of a new cage and new territory, gives the maximum of information about the environment in the safest possible way and thus has important survival value. Perhaps the success and ubiquity of the rat depends as much on this as on any other one factor.

It is easy nowadays to criticize any book of moderate size for its omissions. But in this case the limited size and the restriction to the rat is doubly unfortunate in that several topics basic to the modern study of ethology find no place. Thus, although releasing stimuli are mentioned, there can be no discussion of the relation of these to the filtering processes in the sense organs and in the central nervous system. Again, the significant work of von Holst and von St. Paul on the effects of brainstem stimulation in the domestic fowl, whereby a considerable series of fully co-ordinated and unpractised items of innate behaviour (instinctive acts) are elicited, finds no place. Further, the problem of imprinting and the sensitive period can scarcely be dealt with adequately in a book which is centred around the rat. Yet again it is unfortunate that all mention of the considerable volume of recent work, mostly in the U.S.S.R., which deals with interoceptive conditioning and its relation to conscious and unconscious processes, is omitted. Interoceptive conditioning is in fact classical conditioning in which either the conditioned stimulus or the unconditioned stimulus or both are delivered directly to the mucosa of some internal organ. Interoceptive stimuli are, by their very nature, closely bound up with the life of the organism and they tend to be much more recurrent and regular than do many of the stimuli which impinge from the external world. The study of such stimuli is probably as yet in its infancy and is likely to produce results of great importance in the future. It would have been interesting to have had it related to what is known of the learning powers of the rat as studied by other techniques. However, most of these criticisms derive from the title (reinforced by the sub-title) by which we are led to anticipate a general text-book on the principles of ethology and of behavioural physiology only to find that those subjects for the study of which the rat is not outstandingly good tend to be glossed over or omitted. This is a pity, because the book will be that much less successful in the very important task of presenting ethology to the behavioural psychologists. On the other hand, the work has many good features and will be a useful work of reference. It is attractively produced and the illustrations are excellent, though the price seems somewhat high in relation to the size.

W. H. Thorpe

PLANT HISTOCHEMISTRY

Botanical Histochemistry

Principles and Practice. By William A. Jensen. Pp. vi+408. (San Francisco and London: W. H. Freeman and Company, 1962.) 70*s*.

MICROSCOPIC histochemistry, it is stated, can be regarded as having been founded by the French botanist Raspail, who published work at his own expense after its rejection by a committee consisting of a physiologist, a chemist and a botanist. Raspail stated that the physiologist was ignorant of chemistry, the chemist of microscopy and the botanist of both! Zoologists presumably were uninterested.

Botanists contributed much of the early developments, but latterly 'botanical histochemistry' has not shown the striking advances of 'zoological histochemistry'. Dr. Jensen's book is thus welcome as a stimulant.

It combines the functions of a text on micro-analytical methods with one on methods available for investigations of localization of constituents within tissues. The term histochemistry may possibly include any analytical method but to me (the reviewer) it suggests a chemical technique revealing localization of specific materials within a tissue, rather than straight micro-analysis.

A section of each chapter is devoted to localization technique (termed here microscopic histochemistry): these sections are useful. Many of the methods developed by animal and medical histochemists have been applied to the special structural and other peculiarities of plant tissues. The sections on freeze-drying and freeze-substitution of plant tissues in which Dr. Jensen's own work is significant are timely and useful.

Successive sections deal with general histological procedures and with certain micro-analytical techniques. Techniques for isolation of mitochondria, plastids and nuclei are dealt with. The section on 'histochemical techniques' has chapters dealing successively with carbohydrates and cell walls; proteins; nucleic acids; lipids; minerals; enzymes; autoradiography. 'Minerals' is possibly an odd word to apply to a chapter where microchemical methods applicable to organic phosphate osters are dealt with. Each chapter has a section on localization (staining) procedures and also a section on micro-analytical procedures. It is convenient that these should be compiled together, but the micro-analysis sections do not in several cases compare very favourably with standard texts on microanalysis.

The book is rather obviously designed for the American market as it lists American dealers in equipment and reagents in the United States, materials which in most cases are very easily obtained elsewhere. Local trade names are an inconvenience in scientific literature. Canada balsam is international probably but 'permount' and 'drierite' are local jargon. Misprints occur, such as nitrate instead of nitrite, and uricil for uracil; hyposulfite is presumably dithionite (it is not thiosulphate).

This book should prove to be a valuable stimulant to botanical groups to use some of the techniques proving useful in dealing with animal tissues.

TOWARDS FOOD SCIENCE

Advances in Food Research

Vol. 11. Edited by C. O. Chichester, E. M. Mrak and G. F. Stewart. Pp. ix+454. (New York and London: Academic Press, 1962). 103*s*. 6*d*.

A SCIENTIST who works in the food industry is soon compelled to recognize that his thinking must be done at two levels. Part of it is required to be strictly scientific—the structure of protein, the mechanism of enzyme reactions, the intermediary metabolism of micro-organisms, the determination of the chemical configuration of vitamin B_{12}—these are all examples of topics that would interest a scientific investigator wherever his laboratory might be situated. Other topics, however, for example, continuous dough-making for the plant bakery, the manufacture of potato crisps, the utilization of natural polysaccharide gums in food manufacture need scientific understanding, to be sure, but they also require more diverse talents as well.

The last subject, namely, the use of natural gums in food manufacture, is dealt with by Dr. Martin Glicksman as one of the five long, detailed and well-documented monographs of which *Advances in Food Research* is composed. Dr. Glicksman's article exemplified the second aspect of food research. In it he discusses the use of agar-"structurally . . . still a mystery"—in chiffon pie, doughnut glaze, pickled tongue and sherbet; of carrageenan as a component of eggless 'custard', for the preparation of artificial meat-like products and for converting a mixture of tomato juice, lemon juice and vodka into "high quality Bloody Marys". An equally catholic variety of uses is described for alginates, furcellaran, locust bean gum, guar gum, gum arabic, gum tragacanth and gum karaya.

W. H. Stahl's article on the chemistry of tea and tea manufacture is an admirable survey of the state of knowledge of the subject. It contains a wide review of the literature, including papers from Japan and the Soviet

Union. There are pages of structural chemistry and tables of analyses covering scores of components which, combined, contribute to the flavour, aroma and stimulating action of tea. Figures for vitamin content are listed mainly, it seems, in deference to the Russians, whose view it is that, besides being a pleasant beverage, tea also has significant nutritional and physiological value. Yet in the end, the author is forced to admit that tea tasters and graders tend to be rigid and conservative, to cling to conventional qualities, such as the 'tippyness' of prepared tea, which have little relevance to the quality of what is drunk. Perhaps, indeed, one of the most useful features of this contribution is the definition of such terms as 'brisk', 'tired', 'weathery', 'hungry' and 'common' to which those who carry out research on tea have to give scientific meaning.,

The dichotomy in food research is most clearly apparent in the chapter by S. E. Charms from the Massachusetts Institute of Technology on "The Nature and Role of Fluid Consistency in Food Engineering Applications". This paper is pitched at a high intellectual level. Much of the treatment is mathematical. The concept of fluid consistency is developed theoretically in terms of liquid viscosity and the molecular structure of water. Consistency is then expressed in relation to shear stress and the rate of shear in fluid-flow. This allows different fluids to be classified theoretically as pseudo-plastic, Bingham plastic, dilatant, Newtonian and non-Newtonian. There is a full theoretical treatment of the practical methods for studying such problems of food manufacture as the handling of chocolate couverture and bread dough, the pumping of diverse liquids and the measurement of heat-transfer characteristics. This is indeed the proper application of scientific thinking to practical matters. Yet, at the end of seventy-eight pages, underlining at every point the importance to the food engineer of expressing consistency in terms of fundamental units, there comes the sentence, "at present, little information is available on the fundamental classification of the consistency of food materials."

Of the remaining articles, that by Ludwig Acker deals with enzymatic reactions in foods of low water content, that by Ingmar Bosund with the action of benzoic and salicylic acids on the metabolism of micro-organisms, and that by M. A. Joslyn on the chemistry of protopectin. These, like the rest of the book, are able and comprehensive and of a high standard. Joslyn's long paper, particularly, is a rich pile of ore, mined from the mountain of the literature from which yet more workers must extract the pure metal of the ultimate chemical understanding of a complex large molecule, and, having acquired the knowledge, find out how to use it.

Today, when men of affairs are looking more critically than they did before at the usefulness of scientific research into practical problems, a book like *Advances in Food Research* gives its readers a good opportunity to reflect on how the two ways of approaching food research sometimes complement each other, but sometimes do not.

MAGNUS PYKE

MICROCHEMICAL TECHNIQUES

Proceedings of the International Symposium on Microchemical Techniques

University Park, Pennsylvania, August 13–18, 1961. Edited by Nicholas D. Cheronis. (*Microchemical Journal* Symposium Series, Vol. 2). Pp. xviii+1181. (New York and London: Interscience Publishers, a Division of John Wiley and Sons, 1962.) 300*s*.

THIS publication includes the four plenary lectures, the 123 original papers, and the six contributions on the teaching of microchemistry which were presented at the international symposium on "Microchemical Techniques" sponsored by the International Union of Pure and Applied Chemistry at the Pennsylvania State University during August, 1961.

In early July, 1962, analytical chemists of all countries heard, with a deep sense of personal loss, of the tragic death in a car accident of Dr. N. D. Cheronis, of Brooklyn College, N.Y., who had just completed the editing of the present volume, and whose excellent plenary lecture on "The Characterization of Organic Compounds at the Microgram and Submicrogram Ranges" will be found in Part 2 of this book.

In the same plenary section, D. D. Van Slyke authoritatively discourses on gasometric methods of analysis; E. Sawicki reviews methods for the determination of trace amounts of aldehydes, and R. Belcher describes the work on the development of sub-micro methods for the analysis of organic compounds which is proceeding in his department at the University of Birmingham. The original papers are grouped into sections covering the techniques of (*a*) microscopy, (*b*) inorganic elemental analysis, (*c*) organic elemental analysis, (*d*) functional group analysis, (*e*) chromatographic techniques, (*f*) electro-chemical and radiochemical studies and (*g*) molecular weight determinations and physical properties.

It is obviously impossible in a brief review of this nature to mention more than a small fraction of the investigations detailed by the many well-known contributors. Some papers tend to confuse trace analysis with micro-analysis, but this contentious subject need not be argued here.

E. Wiesenberger presents a fascinating paper on the use of electron microscopy techniques to identify minute amounts of precipitated or electro-deposited materials. Some excellent electron micrographs illustrate this paper. Thermo-micro methods, following the techniques of Kofler and Ludwig, are described by a number of research workers. Chronometric methods are developed by L. Erdey and G. Svehla for molybdenum or tungsten using catalysis of the hydrogen peroxide–iodide reaction. Following the work of J. Haslam in the United Kingdom, J. M. Corliss and C. A. Rush recommend the use of the oxygen flask technique for qualitative organic analysis.

M. Bobtelsky deals with microheterometry, a technique studied in but few laboratories; E. G. Wollish reviews briefly thin-layer chromatography, and H. M. Mongold and R. Kammereck develop its application in lipid radiochemistry. J. L. Brownlee presents a detailed paper on the determination of oxygen in organic compounds using the well-known triton-oxygen interaction to produce fluorine-18. S. Jacobs's method for the quantitative determination of nitrogen in organic compounds by the indanetrione method appears to have advantages over the classical methods. Barbara A. Thompson determines the composition and thickness of thin films by neutron activation followed by γ-spectrometry.

These are but few of the researches described in the present publication. Micro-analysis by combustion, Weiz ring oven techniques, thermo-electric molecular weight determinations, radiometric absorption measurements, Kemula's 'hanging drop' electrode, automated processes, crystalline inclusion compounds of urea and the paraffins. These, and a host of others, are all topics which fall within the ambit of this voluminous survey.

Teachers of microchemistry will find much of interest in Part 10, where the teaching of this subject is exhaustively discussed by experts of long practical experience. The introductory portion of the book, with addresses by Steyermark, Belcher, Malissa and historical contributions by Lieb and Benedetti-Pichler also have an obvious and fundamental educational value.

Despite its high cost, most progressive analysts and research workers will consider it a *sine qua non* to have this book on their reference shelves.

D. T. LEWIS

Advances in Clinical Chemistry

Vol. 5. Edited by Harry Sobotka and C. P. Stewart. Pp. xiv+329. (New York: Academic Press; London: Academic Press, Inc. (London), Ltd., 1962.) 86*s*.

NUMBER 5 is one of the best volumes which have so far appeared in this useful series. As usual the contents cover a wide range of totally unrelated subjects all of which are of present-day importance and the treatment varies from general theoretical discussion to severe practical detail.

The article in Volume 4 on mellituria has been followed up in Volume 5 by an exhaustive account of galactosæmia by L. I. Woolf covering not only the clinical features and the biochemical and genetical aspects but also the details of the laboratory diagnosis and the treatment. This is an excellent example of a molecular disease which lends itself to rational treatment now that the biochemical basis is properly understood. It is proposed to deal with other examples of molecular disease in future volumes.

Another clinical entity which is lending itself to rational therapy now that the nature of the causative factors is becoming less obscure is the malabsorption syndrome which is discussed by A. C. Frazer with special reference to the recent work on the mechanism of the effects of wheat gluten.

Two chapters are devoted to less familiar topics. Haptoglobins are dealt with by C. B. Laurell and C. Grönvall, and peptiduria, a much less well-recognized condition than aminoaciduria, by the late B. Skarzynski and M. Sarnecka-Keller.

The final two chapters are severely practical. H. Baker and H. Sobotka give full experimental details for the microbiological assay of the vitamins of the B group in biological materials, while Bruns and Werners describe the methods for estimating several enzymes, glucose-6-phosphate dehydrogenase, 6-phosphogluconate dehydrogenase, glutathione reductase, methæmoglobin reductase and sorbitol dehydrogenase. Although the treatment is exhaustive, not all clinical biochemists will find the experimental details completely adequate at the bench.

The editors have chosen well for this volume. It is an essential tool in every clinical chemistry laboratory.

J. N. Davidson

Semiconductor Reliability

Edited by John E. Shwop and Harold J. Sullivan. Pp. ix+309. (Elizabeth, N.J.: Engineering Publishers, 1961. Distributed by Reinhold Publishing Corporation, New York; and Chapman and Hall, Ltd., London.) 68*s*. net.

THIS book is based on the 1961 conference on reliability of semiconductor devices and contains twenty-five papers.

We are now reaching a state when the reliability of the newer types of semiconductor devices promises to be so good that it will no longer be a major consideration to the equipment designer. The limiting factors in the reliability of equipment are much more likely to be the interconnexion systems, and methods of incorporating the semiconductor devices into the circuits.

This high reliability of semiconductor devices also brings with it difficulties in measuring failure rates since these are so low. In fact it is almost inevitable that reliability information obtained by ordinary methods of life test will relate to out-of-date devices. This tendency is evident in this book since it is generally agreed that planar semiconductor devices are likely to be the most reliable, and only one paper of the twenty-five deals specifically with planar transistors. However, some of the contributions in the book are important in that they point the way to new methods of life-testing components which may give indications of very long life expectancy from life tests of much shorter duration carried out under overstressed conditions. The paper by D. S. Leck, for example, foreshadows the now widely accepted method of 'step-stress' testing.

An interesting speculation is whether useful information may be obtained by recording small parameter changes during step-stress testing as a barometer of production quality which will enable reliability to be improved even more.

A. A. Shepherd

Compound Semiconductors

Edited by Robert K. Willardson and Harvey L. Goering. Vol. 1: Preparation of III–V Compounds. Pp. xxii+553. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1962.) 25 dollars; 200*s*.

THIS book is a compilation of the work of many authors of original papers on the preparation and properties of III/V compounds. Although the book is largely based on original papers, each chapter has been specially written by the author concerned, and a considerable amount of hitherto unpublished material is included.

Its 53 chapters are grouped into ten sections, dealing with crystal structure, purification of the elements, impurity detection, compound preparation, single crystal growth, thin films, diffusion, segregation, surfaces, and thermodynamic properties of the compounds.

The authors of the book were selected on the basis of a bibliography of more than 1,000 papers on III/V compounds (which is included), and it is obvious that this method of selection has produced one of the most comprehensive and well-written works to date on this subject.

In addition to a thorough theoretical study of the III/V compounds, the book places considerable emphasis on the technology of purifying the component elements and preparation of the compounds in both polycrystalline and single crystal form.

It is extremely well produced by the Reinhold Publishing Corporation, and can be recommended as a necessity for any workers in the field of III/V compounds.

A. A. Shepherd

Proceedings of the International Conference on the Physics of Semiconductors held at Exeter, July 1962

Edited by A. C. Stickland. Pp. xi+909. (London: The Institute of Physics and The Physical Society, 1962.) 210*s*.

IT is a measure of the rate at which semiconductor problems are being worked out that this conference attracted over 130 papers suitable for publication.

The conference, which is the third in the series, the previous ones having been held at Rochester in 1958 and Prague in 1960, has undoubtedly contributed much towards the further understanding of physical phenomena in semiconductors. The papers are divided into sections dealing with transport, disordered semiconductors, effective mass determination, optical properties, lattice vibrations, band theory, magnetic properties, materials, surface effects, and recombination.

It is probably true to say that the sections on transport and optical properties contain much of the work which is providing basic information on electronic states in solids. Although many of the papers are concerned with the properties of germanium and silicon, the range of interest has now been widened; much of the material presented is concerned with what might be described as "second order" properties of metals.

It seems that the diversification of work which is occurring as solid-state physics enters this new phase will lead to a larger number of small, specialized groups working in the various parts of the subject. One fears that as time goes on, unfortunately, such groups will have less and less common ground.

The book has been excellently and promptly produced.

A. A. Shepherd

MAGNETIC ANOMALIES OVER OCEANIC RIDGES

By F. J. VINE and Dr. D. H. MATTHEWS
Department of Geodesy and Geophysics, University of Cambridge

TYPICAL profiles showing bathymetry and the associated total magnetic field anomaly observed on crossing the North Atlantic and North-West Indian Oceans are shown in Fig. 1. They illustrate the essential features of magnetic anomalies over the oceanic ridges: (1) long-period anomalies over the exposed or buried foothills of the ridge; (2) shorter-period anomalies over the rugged flanks of the ridge; (3) a pronounced central anomaly associated with the median valley. This pattern has now been observed in the North Atlantic[1,2], the Antarctic[3], and the Indian Oceans[4,5]. In this article we describe an attempt to account for it.

The general increase in wave-length of the anomalies away from the crest of the ridge is almost certainly associated with the increase in depth to the magnetic crustal material[1]. Local anomalies of short-period may often be correlated with bathymetry, and explained in terms of reasonable susceptibility contrasts and crustal configurations; but the long-period anomalies of category (1) are not so readily explained. The central anomaly can be reproduced if it is assumed that a block of material very strongly magnetized in the present direction of the Earth's field underlies the median valley and produces a positive susceptibility contrast with the adjacent crust. It is not clear, however, why this considerable susceptibility contrast should exist beneath the median valley but not elsewhere under the ridge. Recent work in this Department has suggested a new mechanism.

In November 1962, H.M.S. *Owen* made a detailed magnetic survey over a central part of the Carlsberg Ridge as part of the International Indian Ocean Expedition. The area (50 × 40 nautical miles; centred on 5° 25′ N., 61° 45′ E.) is predominantly mountainous, depths ranging from 900 to 2,200 fathoms, and the topographic features are generally elongated parallel to the trend of the Ridge. This elongation is more marked on the total magnetic field anomaly map where a trough of negative anomalies, flanked by steep gradients, separates two areas of positive anomalies. The trough of negative anomalies corresponds to a general depression in the bottom topography which represents the median valley of the Ridge. The positive anomalies correspond to mountains on either side of the valley.

In this low magnetic latitude (inclination −6°) the effect of a body magnetized in the present direction of the Earth's field is to reduce the strength of the field above it, producing a negative anomaly over the body and a slight positive anomaly to the north. Here, over the centre of the Ridge, the bottom topography indicates the relief of basic extrusives such as volcanoes and fissure eruptives, and there is little sediment fill. The bathymetry, therefore, defines the upper surface of magnetic material having a considerable intensity of magnetization, potentially as high as any known igneous rock type[6], and probably higher, because it is extrusive, than the main crustal layer beneath. That the topographic features *are* capable of producing anomalies is immediately apparent on comparing the bathymetric and the anomaly charts; several have well-defined anomalies associated with them.

Two comparatively isolated volcano-like features were singled out and considered in detail. One has an associated negative anomaly as one would expect for normal magnetization, the other, completely the reverse anomaly pattern, that is, a pronounced positive anomaly suggesting reversed magnetization. Data on the topography of each feature and its associated anomaly were fed into a computer and an intensity and direction of magnetization for each obtained. Fig. 2 shows the directions of the resulting vectors plotted on a stereographic projection. Having computed the magnetic vector by a 'best fit' process, the computer recalculated the anomaly over the body, assuming this vector, thus giving an indication of the accuracy of fit. The fit was good for the case of reversed magnetization but poor for that of approximately normal magnetization. The discrepancy is scarcely surprising since we have ignored the effects of adjacent topography, and the interference of other anomalies in the vicinity. In addition, the example of normal magnetization is near a corner of the area where the control of contouring is less precise. The other example is central where the control is good. In both cases the intensity of magnetization deduced was about 0·005 e.m.u.; this is equivalent to an

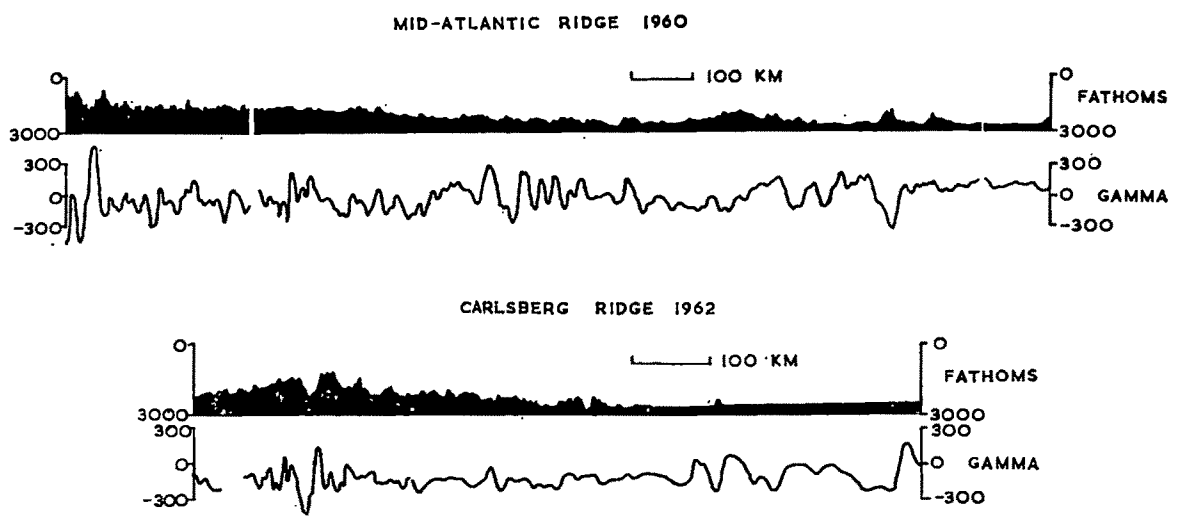

Fig. 1. Profiles showing bathymetry and the associated total magnetic field anomaly observed on crossing the North Atlantic and the north-west Indian Oceans. Upper profile from 45° 17′ N. 28° 27′ W. to 45° 19′ N. 11° 29′ W. Lower profile from 30° 5′ N. 61° 57′ E. to 10° 10′ N. 66° 27′ E.

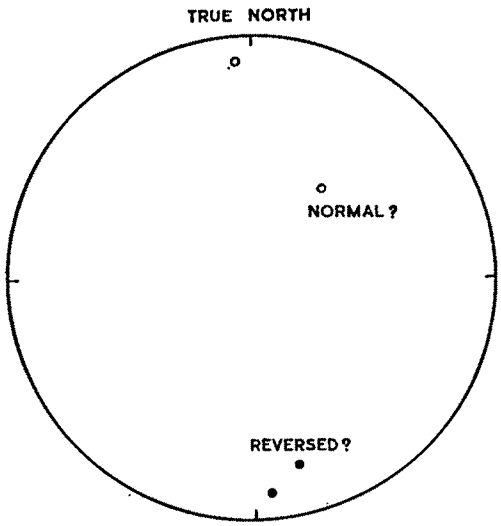

Fig. 2. Directions of the magnetic vectors obtained by the computer programme plotted on a stereographic projection, together with the present field vector and its reverse. Bearings and inclinations: present field vector 356°; −6° (up); computed vectors 038°; −40° (up); 166° 30′; +13° (down)

effective susceptibility of ± 0·0133: (effective susceptibility = total intensity of magnetization (remanent + induced)/present total magnetic field intensity : mean value for basalts of the order of 0·01).

In addition, three profiles, perpendicular to the trend of the Ridge, have been considered. Computed profiles along these, assuming infinite lateral extent of the bathymetric profile, and uniform normal magnetization, bear little resemblance to the observed profiles (Fig. 3). These results suggested that whole blocks of the survey area might be reversely magnetized. The dotted curve in Fig. 3 *B* was computed for a model in which the main crustal layer and overlying volcanic terrain were divided into blocks about 20 km wide, alternately normally and reversely magnetized. The blocks were given the effective susceptibility values shown in the caption to Fig. 4 (3).

Work on this survey led us to suggest that some 50 per cent of the oceanic crust might be reversely magnetized and this in turn has suggested a new model to account for the pattern of magnetic anomalies over the ridges.

The theory is consistent with, in fact virtually a corollary of, current ideas on ocean floor spreading[7] and periodic reversals in the Earth's magnetic field[8]. If the main crustal layer (seismic layer 3) of the oceanic crust is formed over a convective up-current in the mantle at the centre of an oceanic ridge, it will be magnetized in the current direction of the Earth's field. Assuming impermanence of the ocean floor, the whole of the oceanic crust is comparatively young, probably not older than 150 million years, and the thermo-remanent component of its magnetization is therefore either essentially normal, or reversed with respect to the present field of the Earth. Thus, if spreading of the ocean floor occurs, blocks of alternately normal and reversely magnetized material would drift away from the centre of the ridge and parallel to the crest of it.

This configuration of magnetic material could explain the lineation or 'grain' of magnetic anomalies observed over the Eastern Pacific to the west of North America[6]

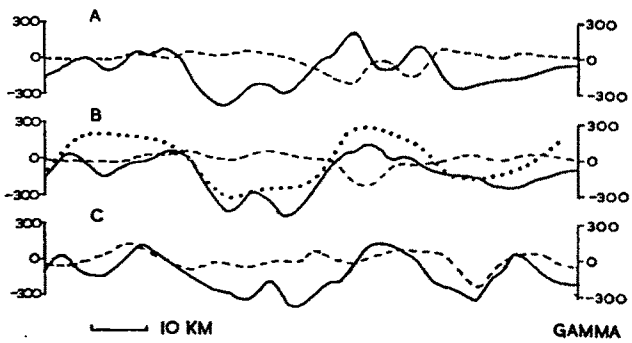

Fig. 3. Observed and computed profiles across the crest of the Carlsberg Ridge. Solid lines, observed anomaly; broken lines, computed profile assuming uniform normal magnetization and an effective susceptibility of 0·0133; dotted line, assuming reversals—see text. The computed profiles were obtained assuming infinite lateral extent of the bathymetric profiles

(probably equivalent to the long-period anomalies of category (1)). Here north–south highs and lows of varying width, usually of the order of 20 km, are bounded by steep gradients. The amplitude and form of these anomalies have been reproduced by Mason[9,10], but the most plausible of the models used involved very severe restrictions on the distribution of lava flows in crustal layer 2. They are readily explained in terms of reversals assuming the model shown in Fig. 4 (1). It can be shown that this type of anomaly pattern will be produced for virtually all orientations and magnetic latitudes, the amplitude decreasing as the trend of the ridge approaches north–south or the profile approaches the magnetic equator. The pronounced central anomaly over the ridges is also readily

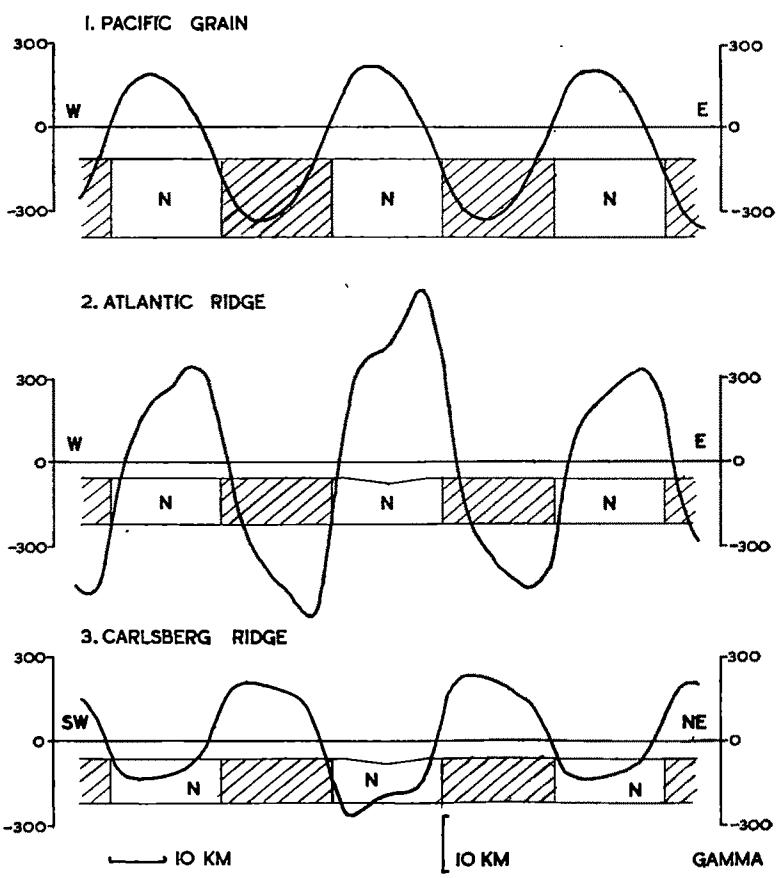

Fig. 4. Magnetic profiles computed for various crustal models. Crustal blocks marked *N*, normally magnetized; diagonally shaded blocks, reversely magnetized. Effective susceptibility of blocks, 0·0027, except for the block under the median valley in profiles 2 and 3, 0·0053

explained in terms of reversals. The central block, being most recent, is the only one which has a uniformly directed magnetic vector. This is comparable to the area of normally magnetized late Quaternary basics in Central Iceland[11,12] on the line of the Mid-Atlantic Ridge. Adjacent and all other blocks have doubtless been subjected to subsequent vulcanism in the form of volcanoes, fissure eruptions, and lava flows, often oppositely magnetized and hence reducing the effective susceptibility of the block, whether initially normal or reversed. The effect of assuming a reduced effective susceptibility for the adjacent blocks is illustrated for the North Atlantic and Carlsberg Ridges in Fig. 4 (2, 3).

In Fig. 4, no attempt has been made to reproduce observed profiles in detail, the computations simply show that the essential form of the anomalies is readily achieved. The whole of the magnetic material of the oceanic crust is probably of basic igneous composition; however, variations in its intensity of magnetization and in the topography and direction of magnetization of surface extrusives could account for the complexity of the observed profiles. The results from the preliminary Mohole drilling[13,14] are considered to substantiate this conception. The drill penetrated 40 ft. into a basalt lava flow at the bottom of the hole, and this proved to be reversely magnetized[13]. Since the only reasonable explanation of the magnetic anomalies mapped near the site of the drilling is that the area is underlain by a block of normally magnetized crustal material[14], it appears that the drill penetrated a layer of reversely magnetized lava overlying a normally magnetized block.

In Fig. 4 it will also be noticed that the effective susceptibilities assumed are two to five times less than that derived for the isolated features in the survey area described. Although no great significance can be attached to this derived intensity it is suggested that the fine-grained extrusives (basalts) of surface features are more highly magnetized than the intrusive material of the main crustal layer which, in the absence of evidence to the contrary, we assume to be of analogous chemical composition (that is, gabbros). This would appear to be consistent with recent investigations of the magnetic properties of basic rocks[6].

The vertical extent of the magnetic crust is defined by the depth to the curie-point isotherm. In the models this has been assumed to be at 20 km below sea-level over the deep ocean but at a depth of 11 km beneath the centre of the ridges where the heat flow and presumably the thermal gradient are higher. These assumptions are questionable but not critical because the amplitude of the simulated anomaly depends on both the thickness of the block and its effective susceptibility, and, although the thickness is in doubt by a factor of two, the susceptibility is in doubt by a factor of ten. Present magnetic declination has been assumed throughout the calculations: it would probably have been better to have ignored this, as in palæomagnetism, assuming that true north approximates to the mean of secular variations; but this is unimportant and in no way affects the essential features of the computations.

In order to explain the steep gradients and large amplitudes of magnetic anomalies observed over oceanic ridges all authors have been compelled to assume vertical boundaries and high-susceptibility contrasts between adjacent crustal blocks. It is appreciated that magnetic contrasts within the oceanic crust can be explained without postulating reversals of the Earth's magnetic field; for example, the crust might contain blocks of very strongly magnetized material adjacent to blocks of material weakly magnetized in the same direction. However, the model suggested in this article seems to be more plausible because high susceptibility contrasts between adjacent blocks can be explained without recourse to major inhomogeneities of rock type within the main crustal layer or to unusually strongly magnetized rocks.

We thank Dr. R. G. Mason and K. Kunaratnam of the Imperial College of Science and Technology, London, for details of the three-dimensional programme used in this work. The programme was originally devised by K. Kunaratnam for a Ferranti *Mercury* Computer. It has been rewritten for use on *Edsac* 2. We also thank the Director of the Cambridge University Mathematical Laboratory for permission to use *Edsac* 2, and Sir Edward Bullard for his advice and encouragement throughout.

This work was partly supported by a grant from the U.S. Office of Naval Research (Contract No. *N*62558–3542).

FORMATION OF STABLE SHELLS FROM PROTEIN SUB-UNITS AS A MODE OF VIRUS SYNTHESIS

By Prof. G. BELYAVIN and Dr. ELIZABETH ROWATT
Department of Bacteriology, University College Hospital Medical School, London, W.C.1

THE structure of virus particles is at present interpreted in terms of the generalized model originally proposed by Crick and Watson[1]. The basis of this model is an outer shell or 'capsid' of individual protein sub-units or 'capsomeres', arranged in a symmetrical manner and surrounding a core of nucleoprotein.

In electron micrographs, virus particles have been found to be either rod-shaped or approximately spherical. The spherical forms in some cases approximate very closely to polyhedra with regularly orientated faces. Given a sub-unit basis for the shell, the solution of virus particle structure depends on the determination of those symmetrical arrangements of individual units which will generate surfaces of spherical, polyhedral or cylindrical form.

The original model postulated by Crick and Watson insisted on a regular arrangement of sub-units in the shell, so that every unit position in the surface is geometrically equivalent. It follows that the forces exerted on each sub-unit by its neighbours are equal throughout, leading to a stable complete shell. The original proposal suggested that these forces might be physical or chemical but made no specific predictions about them. Crick and Watson[1] pointed out that spherical or near spherical shells

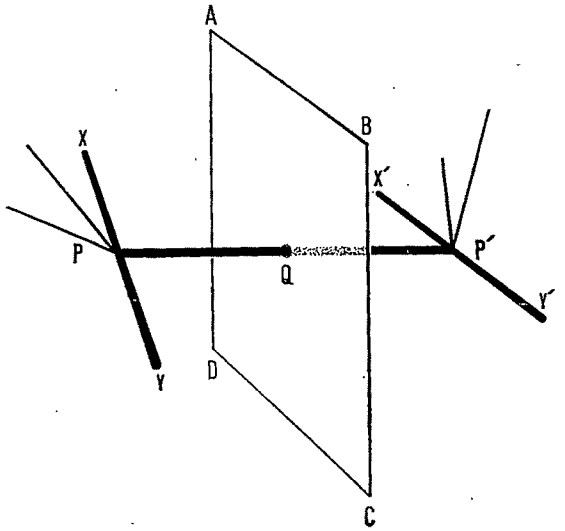

Fig. 1. Linkage of sub-unit axes (P, P') by bond vectors at point Q in common tangent plane ($ABCD$) of sub-unit surfaces

of sub-units probably have cubic point group symmetry which limits the form to structures of 12 or a multiple of 12 sub-units. If more than 60 sub-units are assembled into a shell with cubic, 532 symmetry, the environment of each sub-unit will not be identical and therefore the sub-units cannot be identical.

Negative contrast techniques of electron microscopy have yielded evidence that the particles of many viruses are near spherical or polyhedral shells containing up to 250 sub-units. Such structures cannot be harmonized with the original simple shell model based on 532 symmetry. Kellenberger[2] claims that electronmicrographs of phage-infected bacteria show the formation of a nucleoprotein core of bacteriophage which is later surrounded by a protein shell as if the protein units were joined to the core as to a template. The assumption of a primary linkage between the sub-units and the inner core disposes of any necessity for symmetry in the sub-unit arrangement.

It is well established, however, that tobacco mosaic virus (TMV) rods can be polymerized *in vitro* in the absence of the ribonucleic acid normally incorporated into the hollow cylindrical particle[3]. This resynthesis has not yet been accomplished with any spherical virus, but chemical analysis and electronmicroscopy show that particles of some viruses, for example, polyoma[4] and turnip yellow mosaic virus (TYMV) (ref. 5), occur without the central core of nucleoprotein. The presence of inhibitors of nucleic acid synthesis has caused formation of virus low in nucleic acid in the case of TYMV, an RNA virus[6] and pseudorabies virus, a DNA virus[7], and electronmicroscopy suggested that both preparations contained a high proportion of shells low in, if not actually free from, the nucleoprotein core. This evidence is against the formation of the protein shell on a nucleic acid template, and some other mechanism must be concerned.

The most recent solution of this problem of virus morphology is the 'quasi-equivalence' model put forward by Caspar and Klug[8]. To avoid the necessity of a nucleic acid template, the quasi-equivalence model again stabilizes the shell by the interaction of neighbouring sub-units through the agency of binding forces localized in the form of specific bonds. The essential feature of this concept is the acceptance of bond 'strain' and deformation as an intrinsic property of the model. On these terms each sub-unit does not necessarily have the same environment of sub-units as every other one, but the interrelationship between sub-units is a function of their position in the surface. The variation in mutual sub-unit symmetry may not be very great, but Caspar and Klug were able to show that polyhedral shells with a considerable range of sub-unit number could be assembled using this basic principle.

The quasi-equivalence principle can harmonize the apparent sub-unit morphology and symmetries deduced for a number of virus particles from electronmicrographs, but it introduces a high element of uncertainty into the possible sub-unit arrangement of shells. In purely physical terms, it is difficult to accept a shell built of individual sub-units as a stable structure where large numbers of interconnecting bonds are in a 'strained' or deformed state. It would seem more reasonable to suppose that the fewer the number of strained bonds, the more stable the structure, and such structures are demonstrably much fewer in number than those made possible by the principle of quasi-equivalence.

Random aggregation mechanism of virus assembly as a guiding principle in the interpretation of small virus structures. A consideration of the possible mechanisms of intracellular virus assembly can be a useful guide to the formulation of fundamental structural principles. The nucleic acid coding hypotheses, as understood at present, explain only the synthesis of the protein macromolecules or sub-units from which the viruses are built without any indication of how the morphological units can be assembled in the cell into virus particles. The simplest basic hypothesis applicable in the most general way is the assumption that the synthesized protein sub-units come together in the cell by random collision. The principal merit in this assumption is that this is the basic process of interaction of most particle systems.

The second assumption is that each protein sub-unit carries specific combining sites on its surface, and, if the relative orientation at collision is such as to appose two such sites, binding will occur. The dependence of the resultant shell structure on the shape and size of the sub-units and the surface distribution of their combining sites can be intuitively recognized. The problem is: what variations of sub-unit shape and concurrent arrangement of surface bonding sites will permit the formation of either hollow rods or hollow spheres ? The solution to this problem must be compatible with the circumstances of a random collision process.

Essential parameters defining the form of the stable shell. If two sub-units are bound by the apposition of specific bond sites, the tangent plane common to their surfaces at the point of contact will contain the two linked bond sites. Clearly, the normal to this plane drawn to pass through the point of contact would intersect the respective axes of symmetry of the bond sites in the two sub-units (Fig. 1). This normal may be termed the 'bond vector'.

The essential postulates adopted for the random aggregation model are: (1) That the bond vectors are unstrained throughout a stable shell. (2) That the number of bond vectors and their orientation around the symmetry axes is identical for each sub-unit. (3) That all bond sites are satisfied for every sub-unit in a stable shell. (4) That the number of bond sites on each sub-unit is finite and small.

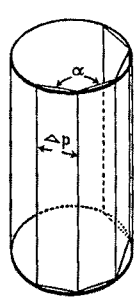

Fig. 2. Arrangement of plane surfaces containing bond vectors of an approximately cylindrical surface

The provision of postulate (1) is equivalent to regarding the sub-unit as being defined by a rigid, non-deformable surface. As the sub-units are protein molecules it may be questioned as to whether this basic assumption regarding the rigidity of surface is reasonable. In fact it is only the location of the bond site in space which is regarded by postulate (1) as being rigidly defined, and this assumption simplifies the overall provisions of the model, and may be acceptable as a reasonable physical property of a polypeptide chain under given conditions.

Postulate (2) ensures that every bound sub-unit is mutually interchangeable with every other in the completed shell: in other words, every sub-unit has an identical environment as required by the original Crick and Watson model.

To ensure that stable shells are built by random collisions, it is necessary that the most stable overall structure (in other words, the most probable structure) is the one in which every active site of every sub-unit is bound, and with approximately equal energy. Such structures will clearly accumulate in the system at the expense of less stable ones. Postulates (1), (2) and (3) make provision for such circumstances.

The restriction of bond site number introduced by postulate (4) is important in so far as it imposes greater limits on the possible relative orientations of the sub-units. As has already been said, the relationship between the number and orientation of bond vectors and the resultant shell structure is the essential problem to be solved. The probable form of the required solution can be deduced from certain geometrical considerations.

It is evident that the regular polyhedra will satisfy all the postulates enumerated here provided that the axes of symmetry for the sub-unit bond vectors are located radially through the vertices, and the corresponding bond vectors coincide with the face margins. The number of face margins meeting in each vertex gives the minimum number of bond vectors per sub-unit necessary for the formation of a given closed surface. This number is equivalent to the number of faces shared by each vertex. For regular polyhedra, excepting the octahedron, this number is 3 or 5 (Table 1). As the polyhedra are regular, each sub-unit is represented by the same number of bond vectors, and the n vectors are orientated in n-fold symmetry around the axes. Other non-regular polyhedra have vertices which share equal numbers of faces, but although these correspond to sub-units with identical symmetries, the n bond vectors are not arranged in exact n-fold symmetry around the bond vector axes. These polyhedra can also be built by aggregation of the appropriate sub-units.

Table 1. Basic Parameters of the Regular Polyhedra

Type of regular polyhedron	No. of vertices	No. of faces	No. of faces shared by vertex
Tetrahedron	4	4	3
Cube	8	6	3
Octahedron	6	8	4
Dodecahedron	20	12	3
Icosahedron	12	20	5

In the case of cylindrical surfaces the appropriate distribution of bond vector axes can be deduced from the fact that any symmetrical planar net can be wrapped around a cylinder to form a continuous cylindrical pattern. If the pattern is to be synthesized from individual units carrying identically orientated bond vectors, linked according to the postulates discussed earlier, certain important restrictions arise. The nature of these restrictions can be indicated geometrically.

A cylindrical surface of radius r may be approximated by the arrangement of p parallel intersecting plane surfaces, so that their intercepts are parallel to the axis of the cylinder and the interval Δp between successive intercepts and the angle between adjacent planes (α) are both constant (Fig. 2). If the intercepts lie on the surface of the cylinder, it is evident that:

$$p.\Delta p < 2\pi r$$

and:

$$\lim_{p\to\infty} p.\Delta p = 2\pi r$$

Similarly it can be shown that:

$$\alpha^0 = 180\ (1-2/p)$$

so that:

$$\lim_{p\to\infty} \alpha^0 = 180^\circ$$

Let a sub-unit be located so that some of its q bond vectors lie in the p^{th} and $(p-1)^{th}$ plane, and the symmetry axis of its bond vectors is coincident with the radial vector of the cylindrical surface at the point of location. If the q bond vectors intersect at a point on their common symmetry axis, then, if they are symmetrically orientated around this axis, all the vectors must lie somewhere on the surface of a cone, whose axis is the symmetry axis of the bonds, and whose apical angle is α'. Each bond vector will then sub-tend an angle of $\alpha'/2$ with the symmetry axis measured in a radial plane. It can be seen (Fig. 3) that for all α' such that $180^\circ > \alpha' > \alpha$ the surface of the cone will intersect the adjacent p^{th} and $(p-1)^{th}$ planes in four intercepts, provided the cone apex lies in the intersection between the planes. Thus only four of the q vectors can link symmetrically with identical sub-units lying on the cylindrical surface. It can also be seen that for $\alpha' = 180^\circ$ and $\alpha' = \alpha$, only two vectors can be formed, disposed in the vertical and circumferential planes respectively. It is clear that in this situation additional bond vectors cannot lie at the same angle to the symmetry axis around which the basic four vectors are disposed. Thus in a six-bond sub-unit, the additional two bond vectors must lie either in the vertical plane parallel to the cylinder axis, or in the circumferential plane. In neither case can they be made completely coincident, by rotation around the six-fold symmetry axis, with the other four bond vectors. If cylinders are made of sub-units with three symmetrically placed bonds, the axes of the sub-units have to be tilted from the radial plane of the cylinder with consequent deformation of bond vectors[9].

It is clear from these geometrical considerations that only a four-vector sub-unit can yield a completely symmetrical unstrained arrangement in a cylindrical surface.

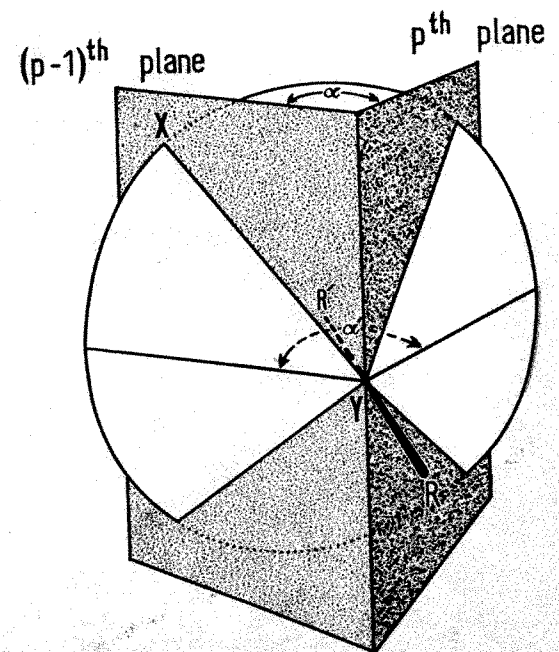

Fig. 3. Arrangement of symmetrical bond vectors forming a cylindrical surface

Conversely the random interaction of sub-units with a complete four-fold symmetry of their bond vectors will yield a cylindrical surface as their most probable configuration. The fact that the vertices of a regular octahedron can be made to lie on a cylindrical surface by placing the centre of symmetry of the octahedron on the cylinder axis confirms the generality of the geometrical deductions discussed above.

It is apparent that the bond vector number must be restricted to 3, 4 or 5, if identical sub-units are to aggregate into uniform spherical or cylindrical surfaces, taking into consideration the basic postulates which have been assumed to govern the aggregating process. The geometrical constructs which have indicated the nature of these restrictions also make it clear that the bond vectors on each sub-unit must be orientated so that they all lie uniformly to one side or the other of a plane which passes through the bond vector origin and is normal to the bond-vector axis of the sub-unit. This would imply that the bond site distribution confers a specific polarity on the sub-unit, a situation which does not seem completely incompatible with an asymmetrically folded polypeptide chain.

Confirmation of the general deductions by geometrical models. Confirmation of the general properties of bond-vector linked configurations of sub-units deduced above has been obtained by the construction of rigid geometrical models[10].

For practical model construction, it was convenient to use plastic skittles, the necks of which were cut off, the bond vectors being represented by large-headed pins thrust through from the inside with the large circular head bearing up against the inside surface. All the 'sub-units' of a set were given identical bond vectors, each pair of which was linked by putting the two shanks of the pins into a sleeve of fine-bore rubber tubing, one from each end. This gave a reasonably rigid link and enabled the requisite number of identically orientated 'bond-vector units' to be built into a complete model. For additional rigidity sleeves of narrow brass tubing could be used. In the completed structure every bond site was satisfied and each sub-unit was identical in bond-vector number and symmetry. The original generalizations could be demonstrated directly from the models, namely: (1) Sub-units carrying 4 bond vectors with suitable orientation in strict four-fold symmetry would result in the assembly of a hollow cylinder (Fig. 4). (2) Sub-units with 3 or 5 bond vectors formed hollow spheres (Figs. 5 and 6). It is important to appreciate that the various types of shell structure produced were determined solely by the bond-vector distributions, as in each case the 'sub-units' were constructed first, and then assembled unit by unit into the completed shell structure.

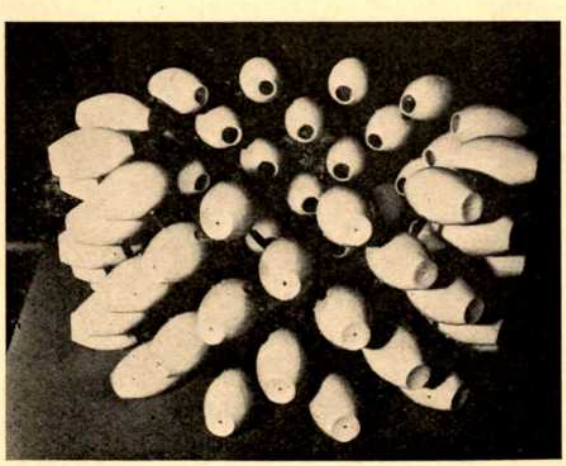

Fig. 4. Model of cylinder made from sub-units with four symmetrical bond vectors

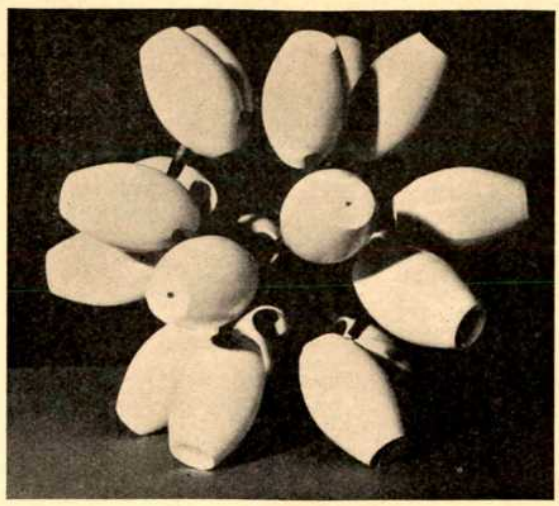

Fig. 5. Model of dodecahedron made from sub-units with three symmetrical bond vectors

Practical experience with this structural approach has emphasized the critical nature of the number of bond vectors and their angular orientation. It is clear, therefore, that if either spherical or cylindrical shells are randomly assembled by the interaction of bonding sub-units according to the enunciated postulates, the probable manner of sub-unit arrangement in the shell is sufficiently restricted in each case to yield a small number of mutually exclusive alternative structures easily compared with experimental observation. It has been possible by these means to deduce structures for certain virus particles which accord extremely well with both electron microscopic and X-ray diffraction data[9].

Nature of the combining sites. Although present theories envisage the virus sub-unit as a solid body with a well-defined and unique surface, these are only convenient representations of a complex macromolecule. Bonding sites, therefore, must be regarded as spatial regions of the macromolecule containing specific chemical configurations. It must be emphasized that the models built according to the postulates of our hypothesis do not in any way lay down *a priori* the shape and form of the sub-units, but only their relative positions in the virus shell and the number and direction of the bond vectors linking them. Thus the position of the bond sites in space is not explicitly defined, but if the particles are symmetrical about the axis intersected by the bond

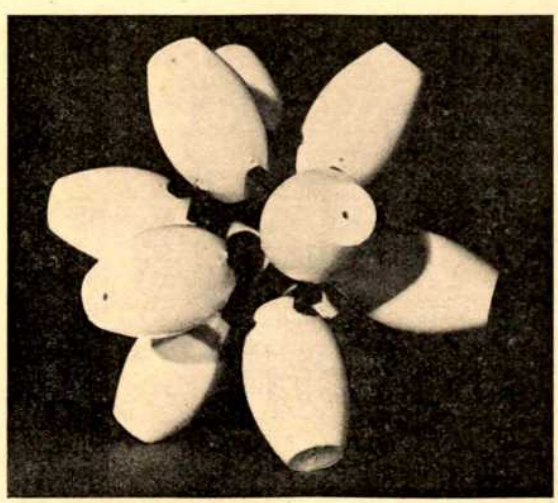

Fig. 6. Model of icosahedron made from sub-units with five symmetrical bond vectors

vectors, the bond sites will lie at the mid-points of the respective bond vectors. No inkling can be obtained from this as to the nature of the bonds but they are probably of a physical kind, such as hydrogen or hydrophobic bonds involving certain specific amino-acid residues in the protein chains of the sub-units.

General scope and consequences of the hypothesis. The random aggregation hypothesis presented in the preceding paragraphs predicts explicitly the relationship between the distribution of specific bond sites on the sub-units of the virus particle and the form of the shell into which they can be aggregated, provided certain postulates are satisfied. The most satisfactory aspects of the proposed hypothesis are: (1) that it can predict the formation of either cylindrical or spherical shells on the basis of common assumptions; (2) that the clear indication of the most probable bond-vector numbers and their orientation for these two types of shell allows a relatively objective formulation of possible sub-unit arrangement. The most important limitation of the hypothesis is that with respect to the spherical or near spherical viruses, the possible sub-unit arrangements that can be deduced from the postulates are not applicable to shells containing more than 60 sub-units, because this is the largest number of identical sub-units which can be arranged symmetrically. Furthermore, strictly polyhedral particles cannot be built as aggregated hollow shells, because the bond-vector orientations of sub-units in plane faces must be different from those at vertices, or face margins. We may ask, therefore, whether a generalized structure model applicable to all viruses can be valid. The most significant observation in this connexion is the size distribution of the spherical or near spherical viruses. The small RNA viruses, including the ARBOR viruses, enteroviruses, and many spherical plant viruses, fall within the narrow size range of 20–40 mμ. The DNA viruses, including several of the typically 'icosahedral' viruses such as the adenovirus[11] and tipula iridescent virus[12], are distributed through an extensive size range from about 60 mμ up to 250 mμ. The extremely restricted size range of the small RNA viruses would suggest a regular shell structure with an upper limiting size, a situation fully consistent with a spherical shell structure as proposed, limited to a maximum of 60 sub-units in the shell. On such a basis, a different structural mode must operate for the formation of the larger viruses.

The hypothesis under discussion has a second element which imposes certain interpretative limitations but which may be of the profoundest significance with respect to the size factors considered in the preceding paragraph. It is evident that the sub-units defined in the shell structure by the bond-vector axes of symmetry are primarily geometrical abstractions. While there can be no doubt that they must constitute the framework on which the actual morphological structure of the related virus particle must be based, their relation to structures seen in the electronmicroscope is not clear. It seems reasonable to assume that the geometrical unit defines the location of a discrete structural element which physically may be no more than a part of a single polypeptide chain. In this respect, it is possible that the geometrically defined sub-unit of the small hollow spherical particle may not be homologous with the morphological capsomere of the large virus. Thus the 'sub-units' of the larger viruses may be aggregates of small protein units which form by random collision, as envisaged in the hypothesis. The units thus formed may be assembled into the virus particle by some other process, such as regular polymerization on to an internal core. It is significant that electron micrographs suggest that many giant protein molecules are assembled from geometrical sub-units into the form of either hollow polyhedra or hollow cylinders[13]. Thus there seems some indication of a structural dichotomy between the large protein molecules and 'small' viruses on one hand, and the 'large' viruses on the other.

One of us (E. R.) is in receipt of a Nuffield Research Grant.

We thank Mr. A. C. Lees for taking the photographs and for helpful suggestions as to their composition, and Mr. V. K. Astor for drawing the diagrams.

The skittle sub-units were obtained from Shipton Plastics, Northwood Hills, Middlesex, to whom we are most grateful. We also thank our colleagues, especially Prof. E. M. Crook, for helpful discussion and criticism.

MANAGERIAL AND COMMERCIAL EDUCATION*

By Dr. J. ROSE
Vice-Principal, Coventry Technical College

THE profound changes taking place in post-war Britain have at last reached the very much neglected field of managerial and commercial education. Although extensive pockets of public indifference and traditional muddle appear to dominate the scene, some progress has already been made. There is, for example, an increasing public interest in education in the field and a growing awareness of the need not only for a managerial *élite* similar to that trained at the Harvard Business School or at some of the French polytechnics but also a recognition that the national interest demands a fundamentally new approach to managerial and commercial education at various levels. In the words of the *Report on Management Studies in Technical Colleges* (H.M.S.O., 1962), "the need is for managers who are able to make intelligent use of various skills and techniques . . . and to use to best advantage the human and other resources at their disposal". The emphasis is on wide horizons, flexibility, planning ability and foresight.

The progress in this educational sphere has been more rapid and extensive in some other countries than in the United Kingdom. In the United States, for example, in 1958, nearly 50,000 students each year took the bachelor's degree, and more than 5,000 the master's degree in business studies, while the number of doctorates in this field was of the order of 100. Western Europe as a whole

* The views expressed in this review are not necessarily those of the Coventry Education Authority.

has accepted management training as a national responsibility at the highest levels of education. In Britain a customary Advisory Council has been set up under the chairmanship of Mr. J. W. Platt and has produced its Report on 1962, a slim but thoughtful document, which might become the basis for a new approach, though it has been very much criticized and somewhat maligned in certain teaching circles. On May 23, Lord Hailsham stated in the House of Lords that management studies are being developed at many universities. Twelve universities are offering courses in management, eight of their post-graduates full time for a period of about a year. Nine universities are to be given special help to expand their facilities. The Foundation for Management Education and the Government are prepared to support these universities as well as one of the colleges of advanced technology and one of the regional colleges of technology in this field. These grants are expected to rise eventually to £100,000 per annum in 1966–67.

Despite these successes progress in the main has, however, been slow, and the impact made on the business world slight. The McMeeking Report in 1959 came out with a devastating indictment of the deplorable situation in the domain of managerial education and commercial education at all levels, citing the 'sitting next to Nellie' complex, the profusion of professional bodies in a given sector of business, their insistence on the adherence to a syllabus set in every detail, and the tragic failure by the banking, insurance and finance firms to grant day-release to even 1 per cent of their young employees (the corresponding figure for the chemical industry is 48 per cent). The Urwick Report on Education for Management in 1947 recommended the establishment of courses which became the basis for commercial and managerial training at technical colleges, but which brought very little improvement. It must also be noted that the technical colleges appear to play a major part in the field of managerial and commercial training in Britain, while the contribution by the universities has not been, so far, impressive.

Commercial and managerial training at technical colleges. A student with passes in three Ordinary Level subjects of the General Certificate of Education can proceed via a part-time-day two-year course, if he is employed, to an Ordinary National Certificate in Business Studies (O.N.C.); a full-time two-year course of studies leads to the Ordinary National Diploma (O.N.D.). A successful student can then continue by part-time study for two years to a Higher National Certificate (H.N.C.) or by full-time study also for two years to a Higher National Diploma (H.N.D.), both being equivalent to a pass degree of a university. In May 1962 there were 8,699 students in the O.N.C. stream, 1,011 in the O.N.D. stream, and 1,450 in the H.N.C. stream. This represents a notable advance over the corresponding figures for the 'fifties.

The neglect of the business studies in the 1950's was mainly due to two reasons: (1) industry and commerce were not interested in this type of training; (2) the professional institutions would not recognize the National Certificates or Diploma as conferring exemption from any of their examinations. Lately, some change has occurred in the attitude of these bodies, and there is a gradual but slow trend towards the recognition of a common course with a flexible syllabus as giving exemption from certain parts of professional examinations. Certain firms—unfortunately few in number so far—are also beginning to take an interest and even support courses leading to higher qualifications, for example, the British Oxygen Co., British Petroleum, Unilever, the Metal Box Co., etc., are sponsoring students for sandwich courses at a number of colleges. At the Regent Street Polytechnic, for example, the five-year sandwich course supported by the General Electric Co. combines business studies with engineering. The Austin Motor Co. is supporting a three-year sandwich course at the Bromsgrove College of Further Education designed to train managers and supervisors. At the Lanchester College of Technology, Coventry, there are two separate H.N.D. courses in business studies, one with special reference to industrial sales and the other with special reference to industrial accountancy; of the 26 students enrolled 20 are sponsored by industry. Other colleges concentrate on the basic business subjects, such as economics, law, accountancy, with some administration, mathematics and statistics.

So far as higher qualifications are concerned, in 1961 a total of 62 colleges granted diplomas in management, while 100 offered courses leading to intermediate level. In that year the numbers of diplomas and certificates granted at colleges were 641 and 812, respectively. Until 1960 there was, however, little enthusiasm in industry for the efforts of technical colleges to train managers. The reasons for this were as follows:

(1) Anyone could enrol to follow a course of management studies, and nearly all students pursued evening courses.

(2) Poor facilities and inadequate teaching combined with unsatisfactory recruitment lead to considerable 'wastage'.

(3) The teachers were unable to carry out research and consultative work owing to the heavy teaching load. (On the average the teachers in this field spend 22 hours a week on contact hours, the corresponding figure in the United States being 10).

(4) Lack of suitable accommodation, unnecessary restrictions and protracted sessions, sometimes of three hours' duration, rendered the teacher's task very difficult.

In general, a tired teacher has been imparting superficial knowledge of many techniques to tired and unsuitable students. However, if the student survived the ordeal, he invariably obtained the College Diploma, for the examination papers were marked by the teachers themselves. The diploma thus lost its value and was largely ignored by the employers. Many firms themselves started managerial training courses, and in certain cases appointed consulting firms to run courses for senior managers. These were residential in character, housed in suitable premises, and the instructors were paid princely salaries in comparison with those of teachers at technical colleges. Oddly enough, there was no diploma at the end of the road, but eventual promotion in industry or commerce. As regards the part played by the management consultants, their long-term objective is education. Member firms of the Management Consultants' Association employ about 1,200 qualified consultants. Some of the firms, as, for example, Associated Industrial Consultants, concentrate on management techniques, others, for example, the Sundridge Park Management, the Production Engineering, Ltd., or the Anne Shaw Organization, hold residential courses for top management; some firms carry out research into new techniques. In the past decade the firms have completed thirty-four assignments to initiate training or personnel development schemes. Consultants have also contributed to education by correspondence courses (H. Whitehead and Partners, Ltd.), lectures, books and articles.

In 1955–56 a Working Party set up by the Ministry of Education investigated this problem, and as a result of their efforts the Ministry published its circular 1/60 in 1960, recommending the establishment of a Diploma in Management Studies. Industry and commerce were expected to sponsor graduate students for sandwich and full-time courses, and the facilities were to be restricted to a limited number of suitable colleges. However, after two years of this experiment the situation shows little improvement. Table 1 shows the comparative figures for 1961–62 and 1962–63.

During 1961–62 nearly 60 per cent of the students attended evening classes only; this has slightly decreased during 1962–63 to about 58 per cent. This proportion is very much greater if one includes the students taking a

Table 1

Full-time sandwich		Block release		Part-time day		Part-time day and evening		Part-time evening	
1961–62	1962–63	1961–62	1962–63	1961–62	1962–63	1961–62	1962–63	1961–62	1962–63
13	31	38	145	155	311	231	525	641	1,348

combined part-time day and evening course. Furthermore, the number of graduates attending the evening courses during 1961–62 was about 150 of a total of 641 students. A large number of students have no academic qualifications; the admission of non-academic students was made possible by the escape clause of the circular according to which students over twenty-seven years of age holding responsible positions are allowed to enrol. The number of colleges offering courses has risen from 32 in 1961–62 to 43 in 1962–63. The proliferation of colleges offering diplomas is probably defeating its main purpose, which is to raise standards by increasing the numbers of full-time courses offered by a few competent institutions recognized to be of high quality as regards teachers, facilities and liaison with industry. According to the director of the British Institute of Management, Mr. J. Marsh (*Technology*, 7 (1), 15; 1963), industry is not yet satisfied that the Diploma is on the right lines.

Thus the old pattern of lack of industrial support and academically qualified students has reasserted itself with some few exceptions, as, for example, in the Lanchester College of Technology, Coventry, where the students are sponsored by industry and the diploma is really a postgraduate qualification. For, as Dr. W. F. Frank, the head of the Department of Management Studies at the Lanchester College, pointed out in a recent letter to *Technology*, management cannot be "taught" as mathematics is; the Diploma course is undergraduate in a sense that the students have no practical managerial experience, and postgraduate in relation to the content of the course and conditions of entry. The important thing for the students is to gain practical experience in industry, which a college cannot provide. At present there are no facilities for technical specialists who are not engaged in management, but who for their own benefit wish to find out something about it. Although large numbers of students attend management courses at various colleges, the prospects for the Diploma are not bright, unless industry can be brought in on a large scale to sponsor students. The urgent task is to persuade the pundits of our economy to depart from the traditional pragmatism and muddle, and in some cases nepotism as well, and to realize that potential managers should go through a specially designed form of higher education, as in the United States and in some Continental countries.

The aim is not just to train young people in techniques and tools of management, such as costing, inventory control, etc., but also in the socio-economic backgrounds of decisions, perception of the total situation, and scientific principles of modern industry. There is an urgent need for a new type of manager with a totally different outlook. This point was emphasized by Mr. J. R. Morrison of McKinsery and Co., management consultants, who pointed out that a radical approach to a complete study of management aspects could bear rich fruit in profitability. Thus one British company with assets of more than £300 million agreed to such a study over a period of four years and the realized saving amounted to tens of millions, though this company had the highest return on its capital in Britain.

At a recent export conference Commander W. E. Whitehead, president of the American subsidiary of Schweppes, told 140 executives that the British industry is failing in the competitive overseas markets owing to the outmoded concepts and faulty attitudes. He emphasized the need for an Institute of International Marketing similar to that at Harvard University. This approach should also apply to personnel management; as the Duke of Edinburgh pointed out in a recent speech to the Institute of Personnel Managers, there is a need for professional training in this field and promoting a careers structure in industry with various levels of qualifications.

The need for competently trained managers has still to be realized by industry. The primary objection sometimes raised against training is the fact that there exists no systematic, conceptual basis of knowledge about management; the theoretical study of managerial techniques, such as accounting, work study of operational research, cannot give a young manager a practical mastery of the art; in other words, management teaching can only render a limited contribution to the normal processes of management, and it is impossible to write down express rules how to run a factory or even a department of a business. This objection is fundamentally true, though to postpone the training until a management science has been created is to ignore the urgency of the problem and the demands of the economy. This is shown by the large sums spent by progressive companies to train their managerial staff, and there is evidence—as the Acton Society's report on *Training Managers* indicates—that the effectiveness of the trainees is increased, since the courses raise their morale, induce self-criticism, influence self-confidence and impart certain skills useful in dealing with difficulties inherent in managerial functions. There is room here for a two-way traffic between industry and educational institutions. Industry could supply a great deal of information to colleges about the internal training methods and organizational problems, and provide constructive criticism about the established courses on the lines already existing in the engineering field. Furthermore, industry ought to provide facilities for academic staff to study managerial problems *in situ* and to 'recharge their batteries', as is already done in various technologies.

Planning for management development is still in its youth; many mistakes will be made and many esoteric proposals will be put forward in this field before maturity is reached. The Acton Society's survey of 1956 (*Management Succession*) showed that of the fifty large British companies investigated, one-third had a comprehensive and systematic management development policy, another third made a feeble attempt at evolving some sort of policy, while the remainder did not evince any interest at all; in most cases comprehensive management planning has only been started after the Second World War. Oddly enough, a survey made by the American Management Association in 1954 (*Survey of Management Development*) disclosed a similar state of affairs, though 2,000 firms were involved. In addition, the concept and *raison d'être* of a manager will have to be elucidated in view of the growing complexity of modern industry.

Perhaps the most comprehensive definition of a manager is that by H. J. Leavitt (*On Training Managers*, 1952), who discards the notion of intellectual supermen and defines the manager as "one whose speciality is skill in the effective integration of many other kinds of specialists . . . a specialist in re-integrating wholes". Leavitt suggests that a manager is in need of skills relating to "an area of creativity and imagination, of insight into relationships among many lists of information". Thus the training of competent managers involves the imparting of knowledge and the development of analytical, synthetic and problem-solving propensities in dealing with men and ideas. Hence

the institutions of higher education have a big part to play in this expanding field, and that involves the universities as well.

According to the Under-Secretary for Further Education, Ministry of Education, in a paper given to the twenty-sixth annual conference of the National Association for Education for Commerce in 1961, large-scale developments in commercial education are likely in the next decade; colleges must be adequately equipped for advanced work and research programmes. In this field of the awakening of public interest the British Institute of Management plays an important part. It has taken a lead in studying the whole subject of management and maintaining a survey of courses in which objectives are analysed and syllabuses and techniques noted. It has also published a conspectus of courses available and is endeavouring to become a recognized centre for the exchange of information and ideas on management education.

Managerial training at the universities. A useful classification of management has been given by A. Cole (*J. Econ. Hist.*, 12, 1946). He envisaged three levels of sophistication; the "empirical", the "rational", and the "cognitive" level. The first is based on experience, and though it has little understanding of the management processes, it has proved to be successful in many cases. Academic training has little to offer at this level.

The "rational" type takes into consideration sophisticated techniques in managing and enterprise; but it is rather indifferent to any changes in the social and economic environment, and the resulting inertia may nullify the gains which come from the use of advanced techniques. At this level most of the training is done by the company training departments consulting firms and technical colleges. Again, the universities were scarcely concerned with training at the "rational" level.

The third or "cognitive" level takes into account the changes in the complex of economic and social events which make up the business environment. It makes use of the practices and ideas developed at the other levels, but at the same time is capable of adaptation to a changing society by engaging in large-scale social research. It has been suggested by Prof. N. C. Hunt of the University of Edinburgh (*BACIE J.*, **15**, 67; 1961) that the role of the academic institutions is to contribute at the "cognitive" level, both in management training and research in subjects such as sociology, economics, psychology and some engineering, while supplementing the work done by consulting firms and technical colleges. Of course, this work can be carried out in addition to the courses leading to commerce degrees—in which the pioneering work was done by the University of Birmingham at the beginning of this century—and to some undergraduate studies in conjunction with social and engineering sciences. For example, Part III of the Cambridge Engineering Tripos includes the study of engineering management; similar courses are run or are being planned at other universities, for example, Edinburgh and Leeds.

The University of Manchester has a School of Management and Administration which organizes courses for practising managers, based on research into the fundamental elements of decision and management. Its aim is to provide managers with information about executive research. On the other hand, a report published in the *Oxford University Gazette* in 1962 considers that the University is not yet equipped for high-grade management studies, while low-grade management studies would not be suitable. The Committee of Social Studies Board, which prepared this report, considers that there is no case for starting in Oxford the kind of diploma course in management or business administration similar to those in some American or other British universities. The report considers, however, that higher management studies, that is, the application of statistical and economic theory to management problems, would be desirable, since they could be developed to a point as a self-contained academic study, as in the United States.

Attempts have been made in universities to develop short, residential courses for established managers, for example, at Oxford, Cambridge, Newcastle, Leeds, Edinburgh and St. Andrews. The Oxford Business Summer School has been running successfully for nine years, and its object is to promote discussions between economics tutors and industrial executives. It is thought at Oxford that courses for business men from three months to a year long are the only sort of business training that could usefully be followed there. The short course at the University of Edinburgh attempts to tackle the problem of increasing specialization in business management and develops a broad understanding of the whole problem of managing an undertaking. In particular, the object of the course is to analyse the impact of the changing social, economic and political environment on the work of a manager; to obtain a clearer view of the interplay of various factors, for example, production, sales, personnel, finance and research; to understand the value of statistical data and their application; and to grasp the human aspect of management. It should again be noted that the participants are industry-sponsored mature individuals, having suitable qualifications and occupying responsible posts in the companies. The course is of three weeks duration and residential, so that the process of learning is continuous and intensive, and emphasis is laid on discussions between the students and interchange of ideas. To broaden the experience of the participants the course is sometimes split into small groups, which discuss selected managerial themes with a member of the staff. The fact that this syndicate work involves managers from a diversity of firms has a salutary effect on those with narrow experience. The course at the University of Bristol consists of two four-week residential periods divided by ten weeks project work in the firm. This sandwich type course implies liaison with industry and a practical aspect.

An interesting development at Edinburgh is the post-graduate course in management studies, which last a whole academic year and is devised for young (25–35 years) managers before they move on to more senior positions, and to graduates in science and technology who are destined for managerial posts. During the year the students return for about four weeks to their firms in order to gather material for their dissertations. The teaching is done by members of the Department of Organization of Industry and Commerce in collaboration with other University Departments, for example, History, Statistics, Political Economy and the Social Science Research Centre.

The problem of co-ordinating academic training with actual works practice is also being tackled by some universities. For example, the new Churchill College sandwich course at Cambridge has been devised in consultation with the Institution of Electrical Engineers in such a way as to relate academic work to industrial practice, and theoretical learning is tested against actual managerial experience. The two-year course at the Manchester College of Science and Technology—the Faculty of Technology at the University of Manchester—is intended for young graduate managers who are working during a part of the period on an industrial problem put forward by their employers; successful candidates are awarded the M.Sc. degree.

Despite these promising advances at the universities, the development of academic training for management has still a long way to go. In a broadcast discussion on the sluggishness in British industry, Mr. F. Zweig expressed the opinion that British management at the upper level lacked imagination, and at lower levels was lacking in leadership. It has been suggested in another broadcast discussion that some of the difficulties were due to the fact that comparatively few able young men had entered

courses in technology in the past hundred years, while professional representation in top management is seldom present. The Chairman of the British Institute of Management, as reported by *The Guardian* on July 1, 1961, stated that administration by men brought up almost entirely in the liberal tradition, who recognized twenty years too late the transcendental power of scientific method, inhibits rapid reaction to change. Hence, compared with American management school graduates, the products of British university and college courses have been termed "magnificiently unprepared" (J. Kitching, *The Observer*, June 4, 1961, p. 24). The two-year course at the Stanford Graduate School of Business leads to a master's degree in business administration, and the curriculum includes both 'pure' and 'applied' subjects. Courses of similar standards are available at some of the Institutes of Technology and the "Ivy League" group, and the subject is viewed there as an academic discipline. In Britain the position is far from satisfactory. It is possible, for example, to obtain a degree at Oxford equipping a student with basic knowledge appropriate to almost any specialized profession but not for business. It has been pointed out by L. F. Urwick (*Manager*, **29**, 608; 1961) that management is a practical art which draws on many disciplines, chiefly economics, engineering, psychology and political science, each of which is an academic subject. However, the integrating character of management runs counter to the universities' tendency towards specialization.

The demands for a business studies school on the Harvard model and similar institutions are gathering momentum in Britain. Various proposals have been put forward to achieve this end, and they are by no means similar. The Foundation for Management Education, which comprises a number of relatively young industrialists, rejected the proposal for one Harvard-type institution for the following reasons: (*a*) lack of suitable teachers; (*b*) uncertainty about the scope and content of the syllabus; (*c*) lack of faith in the viability of such an institution. It has therefore been decided to support a small number of management and business schemes in a restricted number of Universities (Cambridge, Bristol and Sheffield, for example) in the belief that one among them would become similar to Harvard. However, in May 1963 it was announced that the Government and the Foundation were prepared to extend the scheme to nine other universities as well as to one of the colleges of advanced technology and one of the regional colleges of technology. The Foundation, though backed by the Government and the Universities Grants Committee, has been criticized on the grounds that it is encouraging an academic experiment instead of building up a solid course, thus defeating its object of creating an eminent school of business studies.

The idea of a single university becoming like Harvard has been proposed by a small group of people, including Lord Rootes, who wish to see the new University of Warwick as a national centre for advanced business studies. The only criticism levelled so far against this idea is the unavoidable delay involved in establishing the school, while Manchester and others are forging ahead.

Another influential group comprising eminent industrialists and academics holds the view that the schemes proposed by universities or colleges of advanced technology do not match up to industry's need. For example, there is a need for teaching market research and selling, cost analysis, etc., which are not part of academic courses so far. This somewhat critical attitude towards academics and industry is reinforced by some lingering doubts about the facilities at the universities and the motives of the academic staff in establishing management courses.

Despite these divergent views there is an increasing tendency to develop high-grade management courses, and to establish adequate machinery for consultation at national, local and industrial levels between those who provide courses of study and potential users to ensure that the views of both are taken into consideration; hitherto the initiative has come largely from the educationists. Furthermore, the necessity for an eminent school of business studies is supported by the National Economic Development Council in its report *Conditions Favourable to Faster Growth*. It states that "there is a need in this country for at least one very high level new school or institute somewhat on the lines of the Harvard Business School or the School of Industrial Management at the Massachusetts Institute of Technology, either as an independent institution or as a part of some existing university or C.A.T. (College of Advanced Technology)".

A recent survey by Prof. D. Granick (*The European Executive*, 384, Weidenfeld and Nicolson, 1962) examines the managerial problem in Europe at the highest level. He is not impressed by the postgraduate management studies at the British universities, though the Administrative Staff College at Henley has been partly successful, for it attracts first-rate men who are capable of educating themselves. By July 1961, more than 2,500 people, sponsored by a variety of companies, had completed the College course. Their average age was thirty-three, and 40 per cent of the entrants had academic qualifications. The syndicate organization has been developed in order to evolve a wide range of pedagogical devices of great diversity and adaptability; this saves time for experienced and mature students. The significant feature of the course is the relevance and the effective use of prepared resources under pressure of time. This College is a non-profit making venture, and its revenue is derived from fees and subscriptions.

Another point made by Prof. Granick concerns the amateur tradition in British universities and management and the deficiency of enterprise and initiative. This he also ascribes to the lack of able men for management posts, to the tendency to model administration on the Civil Service, and to the relatively low esteem and prestige which business enjoys. Furthermore, scientists and technologists appear to have poor chances of ever reaching the boardroom. The time has come now for universities to play a bigger part than before in management training and research, the latter being essentially a university function. The first object of this research would be—according to W. L. Allen (*Listener*, **66**, 51; 1961)—to convert the blatantly unacademic subject of management into an academic discipline in the form of sociology of industry. Dr. Allen is alarmed at the shape of university management courses; but he feels that the problems set by the complexities of industrial and commercial organizations are such that the intellectual content of management provides a challenge to universities. They must provide the *élite* who ought to be responsible in outlook and professional in conduct. It was suggested at a conference on management training held by the Federation of British Industries in 1961 that the universities should recognize their advantage for a theoretical approach to the subject, while the technical colleges ought to concentrate on the more practical aspects; both types of institutions should recognize that their work and contribution are complementary. The proposals for management studies at some universities and colleges are encouraging, but much remains to be done before we can boast the equivalent of some of the American educational establishments, notably the Harvard Business School. The report of the Robbins Committee, especially the part dealing with higher management education, will therefore be awaited with considerable anxiety and interest. One must also note the strenuous efforts made by the British Institute of Management to reorganize its structure and services and to do some hard thinking about its future policies in the field of management education.

TECHNOLOGY AND THE SIXTH-FORM BOY

By Dr. G. VAN PRAAGH
Senior Science Master, Christ's Hospital

THE Oxford University Department of Education has conducted an enquiry* into recruitment from schools into higher scientific and technological education in England and Wales, and has made an attempt at a comparison with the situation in Sweden, Holland and West Germany.

It is sometimes said that boys tend to read some form of applied science or engineering only when they cannot get a place in faculties of pure science, that is, that the best boys read the pure sciences, and the applied sciences get the rejects. The evidence from the enquiry seems to support this view, and to show that in Great Britain pure science attracts three times as many top-grade boys as does engineering, and that the position is reversed in the case of the lowest grade boys; three times as many read for engineering degrees or Diplomas in Technology as for degrees in a pure science. The question was first considered at a colloquium held in March 1961, the members being drawn from schools, universities, colleges of technology, industry and Government departments. This was followed by a one-day conference of school and university teachers in June 1961. Data were then obtained from three main sources: a study of Advanced Level results, questionnaires completed by sixth-form boys, and interviews in schools. The enquiry covered 121 schools and was concerned with 1,459 boys who had taken the Advanced Level examination. Statistics from these examination results showed that about 65 per cent of boys in the top Advanced Level grading went on to read for degrees in pure science and only about 20 per cent to read engineering. In the lower grades, 2–6, the latter percentage rises through 25 per cent for grade 2 to 60 per cent for grade 6, whereas the percentage reading pure science falls from 60 per cent for grade 2 to 20 per cent for grade 6. These figures fully support the view which the enquiry set out to investigate.

However, some agree that it is best for the future technologist to have a basic education in pure science at the university, followed by a practical training in the particular technology in which he is going to work: "The more intellectually able he is, the later should be the stage at which he moves from the field of pure to applied science". Those who take the opposite view say: "for some of the ablest minds the best approach to applied science is a course where problems of application feature strongly at quite an early stage—this may even be the best approach for some of the best pure scientists".

The latter view assumes that there is adequate practical training provided by industry for pure science graduates. It is doubtful whether this is so, and many industries prefer to take future graduates for a year's training before they go on to university. It would be interesting to know what percentage of these trainees, who had chosen pure science as their university course, change to applied science after this year of industrial experience.

The enquirers were also concerned with the reasons for this state of affairs and attempted to discover these by means of questionnaires, interviews, etc. They sought to find out at what stage boys make the choice between arts and science, and then at what stage they choose a career in pure or applied science. The results showed that the great majority of boys do not seem to make the latter decision until they are in the sixth form. The external factors influencing the choice are listed, and percentages are given of boys who had discussed their careers with parents (94 per cent), subject master (37 per cent), headmaster (34 per cent), careers master (29 per cent), friends (27 per cent), and youth employment officers (17 per cent). Only 12 per cent of the sample said that their choice had been influenced by previous knowledge of the career, that is, through reading, hobbies, vacation work, courses, lectures, etc. Boys' knowledge of technology was vague: on the whole, they think technologists are the products of technical colleges, and confuse them with technicians. Very few knew the abbreviation "C.A.T.".

The conclusion seemed to be that a major factor in a boy's choice is the 'public image' of the two careers: scientists, boys believe, are educated at universities, and go on, if they are fortunate, to 'do research'; research is glamorous, interesting, leads to exciting discoveries, is not really 'work' and may well make you famous. Technologists, on the other hand, are educated at technical colleges, have lower social prestige, are less intelligent and well paid, and their work is 'boring'. The authors have been at pains to find out what a boy means by saying that a job is 'interesting' or 'boring' and came to the conclusion that "in most cases, the terms are simply grunts of approval or disapproval and are probably related to the degree of ignorance of the job concerned".

The Right Hon. W. F. Deedes, Minister without Portfolio, thinks parents are largely to blame for the social attitudes and prejudices which govern the choice of professions and careers in Britain. Speaking at a school prize-giving recently, he said that high status was attached to careers in the Foreign Office, the law, the City and natural science. Lower status attached to being an electrician, a salesman or an engineer. "These prejudices are landing us in difficulties. We are becoming chronically short of able young men in the technical professions. There is much talk of the so-called 'brain drain' from science. We have more cause to worry over the failure of British engineering to attract the best young brains."

One thing is very clear. At this critical stage in a boy's life, the transition from school to higher education, the sixth-former is in very serious need of more information, counsel and guidance. Every school with a sizeable sixth form should have a careers master who is given the facilities to do the job properly, that is, time-off and secretarial assistance. He could probably not teach more than half a timetable, if that. Headmasters, form-masters, house-masters have not the time to make themselves knowledgeable in this field, nor to pass on the necessary information to the boys. Lectures, films, visits, short courses in the holidays, in addition to repeated personal interviews with each boy during the whole of his sixth-form period, are needed.

Britain's need for technologists is well known; are the amateurish and haphazard ways in which boys enter technological training equally well known?

NEWS and VIEWS

Organic Chemistry at Sheffield : Prof. W. D. Ollis

Dr. W. D. Ollis, at present reader in organic chemistry at the University of Bristol, has been appointed to the chair of organic chemistry at the University of Sheffield in succession to Prof. R. D. Haworth (see *Nature*, **199**, 21; 1963). Dr. Ollis graduated at the University of Bristol and was appointed to the academic staff in 1946. Dr. Ollis's earlier research work, in collaboration with Prof. W. Baker, was concerned with various aspects of organic chemistry, including the investigation and establishment of the novel aromatic structures of a widely varying group of heterocyclics now termed 'meso-ionic' compounds, of which the sydnones are representative, the study of the formation and stereochemistry of macrocyclic compounds of the salicylide, cresotide and thymotide types, and the synthesis of isoflavones. His continued research work on the chemistry of natural products has been widely based, including synthetic, structural and biosynthetic studies on plant products and fungal metabolites. Structural investigations, involving extensive use of modern physical methods, have led to the recognition of several new groups, including the biflavonyls and the dalbergiones, as well as structural variants of the isoflavanoids. The results of his work on the Gymnosperms and members of the Leguminosae family are of considerable phytochemical interest. In 1952 and 1953, Dr. Ollis was a member of the group under Prof. R. B. Woodward, of Harvard University, who achieved the total synthesis of strychnine, and in 1962 he was visiting professor at the University of California, Los Angeles.

Chief Oceanographer, Marine Sciences, Canada: Dr. N. J. Campbell

Dr. Neil J. Campbell, oceanographer-in-charge, Atlantic Oceanographic Group, Fisheries Research Board, has been appointed chief oceanographer, Marine Sciences Branch, Department of Mines and Technical Surveys, Canada. A marine physicist, Dr. Campbell has had several years of experience in oceanography, particularly in the Arctic. Since 1959, he has directed the activities of the Atlantic Oceanographic Group's oceanographers and marine biologists in their investigations of Atlantic and sub-Arctic waters. Born in Los Angeles, he obtained his B.Sc. and M.Sc. from McMaster University in 1950 and 1951, respectively, and his Ph.D. in physics from the University of British Columbia in 1955, attending the Institute of Oceanography there. During this period he participated in a joint U.S.–Canadian Beaufort Sea Expedition in a study of the properties of western sub-Arctic waters off Canada's northern coast. On graduation, Dr. Campbell joined the staff of the Oceanographic Group of Fisheries Research Board in Nanaimo, British Columbia. Later, he was transferred to the Board's Biological Station at St. Andrews, New Brunswick, to take charge of an oceanographic programme of the Canadian Arctic. Under this programme he directed and participated in 1955 and 1956 in two Arctic cruises to Hudson Strait, Foxe Basin and Lancaster Sound. He remained in charge of this programme until 1958, during which time he directed one phase of the International Geophysical Year oceanographic project, 'Deep Water Circulation'. In 1960 and 1961 he acted as scientist-in-charge of joint cruises of the Atlantic Oceanographic Group with Dalhousie and Columbia Universities, which carried out geological investigations of the Earth's crust in the north-west Atlantic Ocean. Dr. Campbell is now a Canadian citizen.

The 1963 Soviet Antarctic Expedition

A British glaciologist, Dr. Charles Swithinbank, is to join the ninth Soviet Antarctic Expedition which is preparing to leave Leningrad in the autumn in the Diesel-electric ship *Ob* and motorship *Co-operatsiya*. This will be the first time a British scientist has participated in a Soviet Antarctic expedition. French scientists will also work with their Soviet colleagues in the Antarctic. They will be flown from Mirny to the *Vostok* station, where they will study the dynamics of the movement of ice. Pavel Haloupka (Czechoslovakia), well known for his work on cosmic rays, will be spending his second winter in Antarctica. There will also be an exchange of scientists between the expeditions of the U.S.S.R. and the United States.

The Building Research Station and the Road Research Laboratory

In reply to questions in the House of Commons on July 30, the Parliamentary Secretary for Science, Mr. D. Freeth, said that the non-industrial staff of the Building Research Station would increase by about 6 per cent in 1964–65 and improved facilities would be available in the new physics laboratories opened earlier in July. The gross expenditure of the Station had risen from £781,000 in 1961–62 to an estimated £970,000 in the next financial year, and he fully agreed that there was an increasing volume of research for the Station. The Department of Scientific and Industrial Research expected to award up to 2,010 postgraduate studentships this year, an increase of 24 per cent on 1962, and the value of the awards was increased by an average of 23 per cent last year. Mr. Freeth also said that the Road Research Laboratory examined the specifications of all motorway and trunk road schemes costing more than £1 million, and monthly liaison meetings were held between the Laboratory and the Ministry of Transport to discuss problems arising from road schemes. When appropriate, visits were paid to schemes in progress. If questions arose on which the advice of geologists and pedologists elsewhere in Government service would be valuable, it could readily be obtained.

The National Centre for Scientific Research, Paris

In the year ended September 30, 1962, the budget of the National Centre for Scientific Research, Paris, exceeded 308,000,000 new francs—an increase of 54 million francs on 1960–61 (Centre National de la Recherche Scientifique, Paris. Rapport d'Activité, Octobre 1961–Octobre 1962. Pp. 440+4 planches. Paris: Centre National de la Recherche Scientifique, 1963.) Of this, some 211 million francs was for functional services, 85 million francs for equipment, and almost 6 million francs for grants for the institution of new activities. The number of research workers increased from 3,409 in 1961 to 3,773, and of these, 3,045 were working in the natural sciences and 762 in the human sciences, compared with 2,712 and 674, respectively, in 1960–61. The report for the year is in three parts. The first reviews briefly the general services given to scientific research, including the provision of equipment, assistance to publications, international exchanges, documentation, etc. The second reviews briefly the activities of the research groups which are not located in the research centres attached to the National Centre itself. These range over the mathematical, terrestrial, and human sciences, physics, chemistry, biology and medicine. The third part summarizes the work proceeding in the several laboratories of the

National Centre itself and in those attached to it such as the Laboratories of Bellevue and of Gif-sur-Yvette, the Centre for Nuclear Research, Strasbourg, and the Centre of Scientific, Industrial and Maritime Research, Marseilles, as well as the activities of the various scientific Commissions. The report displays an impressive range of scientific activities, but seldom gives more than the titles of investigations, and lists of published papers are not included.

Scientific Research in Belgium

THE thirty-fifth annual report of the National Foundation for Scientific Research, Brussels, covers the year ended September 30, 1962, in which grants totalling some 70 million francs were authorized (Pp. 349. Brussels: Fonds National de la Recherche Scientifique, 1963). For 1962–63 grants and subsidies totalling 85 million francs have been budgeted. A special grant of 100,000 francs was made to the Scientific Station of Jungfraujoch, where biological investigations have been resumed. Grants totalling 17·5 million francs were made to the Foundation for Scientific Medical Research: a list of individual recipients of grants and of the subjects of their investigations is included in the report. Grants totalling some 3·7 million francs have also been made for radiobiological research with isotopes and for cancer research at the Universities of Brussels, Ghent, Liège and Louvain, and in all some 24 million francs were awarded during the year for research in the hospitals attached to these universities and in other hospitals and special institutes. The bulk of the report comprises annexes, including an alphabetical list of the 593 recipients of grants, their subjects of investigation and publications during the year, as well as those of 146 foreign recipients of grants, 25 of whom were outside Europe. The report gives the usual details of membership of scientific commissions, etc.

The Nordisk Institut for Teoretisk Atomfysik

AT the end of the academic year 1961–62 Nordita (Nordisk Institut for Teoretisk Atomfysik) completed its fifth year, though it is still continuing on an interim basis (Annual Reports, 1960–61 (pp. 20), and 1961–62 (pp. 32). Copenhagen: Nordita: Nordisk Institut for Teoretisk Atomfysik, 1963). The Board consisted of professors from Denmark, Finland, Iceland, Norway and Sweden, with the late Prof. Niels Bohr as chairman. Mr. L. Neilson of the Danish Ministry of Finance acted as secretary to the Board, and Dr. G. Funke, secretary-general of the Swedish Atomic Energy Research Council, Stockholm, assisted the Board in an advisory capacity. On June 30, 1962, the scientific staff of Nordita consisted of the director, C. Moller, G. E. Brown, B. R. Mottleson, L. Rosenfeld, S. Rozental and A. Winther. Seventeen Research Fellows held appointments during the year. Two visiting professors, R. E. Cutkosky from Pittsburg and E. H. Wichmann from Berkeley, gave lectures and guided the Fellows in their work. The titles of the various courses of lectures, including those given at the Institute for Theoretical Physics, University of Copenhagen, and of the colloquia, together with the papers published and issued as *Nordita Publications* and five volumes of lecture notes, are listed in detail in the annual report, which as usual is printed both in Danish and English. The publications and lecture notes are obtainable free of charge by institutions and physicists interested.

The Organization for European Co-operation and Development

THE Organization for European Co-operation and Development, which on September 30, 1961, succeeded the Organization for European Economic Co-operation, is briefly but fully described in an admirable brochure under that title (Pp. 254. Paris: Organization for Economic Co-operation and Development, 1963). To the three chapters which describe successively the history of the Organization, its aims and tasks, and its structure and functions—the last of which sets out the functions of the Committee of Scientific and Technical Personnel, the Committee for Scientific Research, the Industry Committee, the Energy Committee, and the European Nuclear Energy Agency—there are appended the convention establishing the Organization, the rules of procedure, the statute of the European Nuclear Energy Agency and the text of the European Monetary Agreement and the Codes of Liberalization of Capital Movements and of Current Invisibles.

Radiation Protection Norms

REVISED radiation protection norms were approved by the Council of the Organization for Economic Co-operation and Development on December 18, 1961, in place of those previously adopted on June 12, 1959. The revised norms are given in the booklet *Radiation Protection Norms* (Pp. 44. Paris: European Nuclear Energy Agency, Organization for Economic Co-operation and Development, 1963). They were prepared by the Health and Safety Sub-Committee of the Organization for Economic Co-operation and Development European Nuclear Energy Agency, and take account of recent developments in scientific knowledge and the latest *Recommendations of the International Commission on Radiological Protection*. Some of the maximum permissible dose values and most of the limits of concentration of radionuclides in drinking water and in air inhaled have been altered, but they are still based on the same principles as those previously adopted. The four main sections of the booklet deal with occupational exposure in controlled areas, exposure of special groups of the population, exposure of individual members of the population, and exposure of the population as a whole, and the appendixes list specific data regarding maximum permissible doses and concentrations of radionuclides in drinking-water and in air inhaled. The maximum permissible whole-body dose for persons in controlled areas is governed by the formula $D = 5(N-18)$, where D is the tissue dose in rems and N is the person's age in years. Protective devices should be based on an average weekly dose of 0·1 rem and the maximum dose accumulated during any thirteen consecutive weeks must not exceed 3 rems. There are permitted variations in certain circumstances. The maximum permissible whole-body dose for persons not in controlled areas varies from 0·5 rem per annum according to the particular group, and for all individual members of the general population is 0·5 rem per annum. The maximum permissible genetic dose for the population as a whole is 5 rems *per capita* accumulated to the age of thirty years. The booklet does not indicate where the revised norms differ specifically from those of June 1959.

Co-ordinate Colour Identification for Industry

THERE has long been in industry and science a need for a precise method of classifying and identifying colours. The National Bureau of Standards (NBS) *Technical Note* No. 152 (Pp. ii+9. Washington, D.C.: Government Printing Office, 1962. 15 cents), entitled *Co-ordinated Color Identifications for Industry*, by K. L. Kelly, describes a method of co-ordinating the five levels of fineness of colour designation, which was developed by the Inter-Society Colour Council Subcommittee (ISCC) for Problem 23, "The Expression of Historical Colour Usage". It is based on the ISCC–NBS method of designating colours given in the National Bureau of Standards *Circular* 553 (1955), which also includes a dictionary of colour names, and it lists the methods for changing from one level to another. Examples are given of the use of each level.

Ion–Atom Collisions

THE National Bureau of Standards *Technical Note* No. 185, entitled *Lectures on Ion–Atom Collisions*, by M. R. C. McDowell, at present at Royal Holloway College, London, consists of six lectures delivered at the Joint

Institute for Laboratory Astrophysics (Boulder, Colorado) during September 1962 (Pp. iv+66. Washington, D.C.: Government Printing Office, 1963. 40 cents). The material for the first four lectures on the impact parameter formulation of the theory of atom–atom collisions, the application of the first Born approximation, slow charge transfer, and charge transfer in other cases, respectively, was largely taken from the work of D. R. Bates and was presented for pedagogic purposes only. The other two lectures, dealing with further remarks on charge transfer and the ionization of atomic systems by fast protons, contain original material. The numerical results quoted are taken, in part, from at present unpublished work by M. B. McElroy (Belfast), Rudd and Jorgenson (University of Nebraska) and the author.

Seismology in New Zealand

In addition to the main earthquake observatory at Wellington, the New Zealand Department of Scientific and Industrial Research operates stations at some sixteen other places, together with seismographs at Hallett Station and Scott Base in Antarctica. Records of observations are given in the reports for 1955–57, now available (New Zealand Department of Scientific and Industrial Research: Geophysics Division. Wellington: Government Printer). During 1955, 84 shocks were reported felt by people in New Zealand, and one in the Cheviot region did minor damage. Most of these epicentres were in or near New Zealand, but on February 27 an earthquake in the Kermadec Islands (magnitude about 8) was felt in Tolaga Bay and in Wellington. During 1956, 131 earthquakes were felt in New Zealand, including two which did some damage. The most severe was on December 28 between Opotiki and Tolaga Bay (magnitude 6·4) and the other occurred on March 2 some 10 miles north-west of Tokaanu (magnitude 5·3). During 1957, 88 earthquakes were reported to be felt in New Zealand. The shock of December 31 (magnitude 6·6) had an epicentre about 100 miles west of Milford Sound. Damage to chimneys occurred as far west as Dunedin. Minor damage was done by earthquakes on February 22 in the Ohakune–Raetihi district, on March 13 from the Bay of Plenty to Greymouth, and on September 26 between New Plymouth and Wellington. The earthquake reports for 1958 and 1959 are not yet ready, but during 1960 two earthquakes caused minor damage. That on May 25 had an epicentre at sea some 20 miles north of Milford Sound, and that on February 21 was north of Canterbury. Two earthquakes from foci estimated at 370 miles depth occurred on March 23 under N. Taranaki.

In order to facilitate the study of near earthquakes, G. A. Eiby and M. G. Muir, of the Wellington Seismological Observatory, have compiled some most convenient seismological tables from the Jeffreys–Bullen tables (New Zealand Department of Scientific and Industrial Research: Geophysics Division. *Tables to Facilitate the Study of Near Earthquakes*. Seismological Observatory Bulletin *S*-109. Pp. 31. Wellington: Government Printer, 1961). These are: travel time of P for a given S–P interval; distances corresponding to given times of P, S and S–P; distances corresponding to given travel times of P and S; phases due to crustal structure (Pg, P^*, Sg, S^*); intervals between Pn, Sn and crustal phases. They also give a nomogram for earthquake magnitudes after Richter.

Ultra-structure of Nucleoli and Chromosomes in Normal and X-irradiated Liver Cells

Electron microscope studies on chromosome structure, although fruitful, have never fulfilled the somewhat optimistic hopes which were originally held out for their use in this particular biological field. The difficulties which have been encountered are not simply due to poor fixation, but result from the lack of contrast between chromosome structures and other nuclear materials. The use of 'Araldite' embedding coupled with phosphotungstic acid staining is reported by J. M. G. Davis, of the Department of Radiotherapeutics, University of Cambridge, to overcome partly this problem of nuclear contrast and to make possible studies on changes in chromosome and nucleolar structure during cell development (*Phil. Trans. Roy. Soc., B*, **291**; May 16, 1963. 21*s*. or 3.15 dollars). He describes the changes observed in these structures in rat liver cells stimulated to undergo mitosis by partial hepatectomy, observations being made during the early stages of regeneration and throughout mitosis in both normal and X-irradiated animals. A relation was shown to exist between a change in nucleolar structure from a compact to a diffuse state, due apparently to the loss of pars amorpha, and the formation of new double membraned elements of the endoplasmic reticulum (alpha cytomembranes). The suggested relationship between these two events is reinforced by the observation that shortly after the irradiation of animals with 450 r. of X-rays, both the formation of new alpha cytomembranes and the correlated nucleolar changes are inhibited. This is an important observation, particularly in view of the present interest in the transfer of ribonucleoprotein from the nucleus (nucleolus) to the cytoplasm. It is also of interest to note that this is one of the first reports demonstrating an inhibiting effect of X-rays on a normal sequence of changes in nuclear ultra-structure, and that this inhibition was evident in the first few hours after irradiation. The chromosome studies reported showed that at prophase each chromosome appeared as a strand, 1000 Å in diameter, made up of a dense aggregate of a number of thin 100 Å fibres. In mitotic cells fixed 15–30 min after an X-ray dose of 450 r., no ultra-structural changes could be demonstrated in the chromosome material, but with high doses of 2,000 r. a change in the density of packing of the 100 Å fibres was noted together with some indications of fragmentation of metaphase and anaphase chromosomes.

Nomad Fulani

A monograph, published under the ægis of the Institut d'Ethnologie, Paris, deals with the social structure and economy of the Wodaabe Fulani, who form the bulk of the nomadic Fulani inhabiting the Sahel zone between the Nigerian boundary and the desert and steppes of the Air region of the central Sahara (*Travaux et Mémoires de l'Institut d'Ethnologie*. Nr. 64: *Peuls Nomades: Étude Descriptive des Wodaabe du Sahel Nigérien*. Par Magguerite Dupire. Pp. viii+336+27 planches. Paris: Institut d'Ethnologie, Musée de l'Homme, 1962. 45 francs). The fifty-page introduction, which summarizes the work of other people and which attempts a description of the physical type of the Fulani and of their zebu cattle, is based on quite inadequate biometrical data in the case of the human types and on purely hypothetical migration routes in the case of their beasts. The author is on surer grounds when she comes to her own material, and she divides it into four parts, which deal respectively with the economy, the domestic cycle, Fulani marriage, and with Wodaabe lineage and tribal organization. There are twenty-four plates, fifteen diagrams and sketch maps and one very large map giving details of group migrations and of transhumance routes in the area. Altogether it forms a very valuable addition to Fulani ethnography, the more so since a complementary study of the Wodaabe living south of the Nigerian border has already been made by D. J. Stenning (*Savannah Nomads*. International African Institute, 1959).

The Royal Scottish Museum

With the approval of the Scottish Education Department, a panel of honorary curators has been appointed at the Royal Scottish Museum, Edinburgh. In the report

for the year 1962, the Director states that the function of the panel is purely advisory and it helps to extend greatly the body of specialist knowledge on which the Museum can call. The Director also directs attention to the recruitment of senior officers in museums as a matter which is giving increasing cause for concern. Such posts can be very rewarding to academic individuals especially if they are interested in certain techniques for spreading knowledge and have an original turn of mind. Unfortunately, universities appear to produce fewer and fewer suitable candidates and, for example, it is rare to find an honours graduate in zoology prepared to undertake research in taxonomy. It is pointed out that the Museum has been deprived of the full use of the north-east and north-west wings ever since their structural shortcomings were detected almost twenty years ago. At the best, it will be another three years before they can be reconstructed and equipped.

The Western Australian Museum, Perth

In 1960, the Art Gallery of the Western Australian Museum, Perth, was separated from the Museum premises and a programme of building alterations was immediately commenced (Annual Reports, 1960–61 (pp. 40), and 1961–62 (pp. 43). Perth: Western Australian Museum, 1962). As a result, the staff has at its disposal modern and well-equipped accommodation, a satisfactory library, and good storage facilities for a large part of the collections. As a natural sequence to these improvements, plans were made for the modernization of the exhibition galleries, and these included a rapid-change display case. The report for 1960–61 gives details and plans of this ingenious showcase. In 1961–62 the most important development in the educational services provided by the Museum was the creation of a new Children's Centre. Here specimens could be handled and the pattern followed which is now accepted in many museums schools services. The field work organized by the Museum was extensive and linked both with the Museum collections and the individual research work of members of the staff.

Pugwash Conference in Yugoslavia

Some sixty scientists from two dozen countries will meet in Dubrovnik (Yugoslavia) on September 20 to discuss the crucial problem of how to achieve world-wide disarmament and security. Their meeting, which continues until September 25, is the eleventh in the series of Pugwash Conferences (Conferences on Science and World Affairs) and follows the two held in Cambridge and London in the autumn of last year. The title of the Conference is "Current Problems of Disarmament and World Security", and it will lay particular stress on the part that non-aligned nations can play in disarmament and the possibility of setting up nuclear-free zones in Europe and elsewhere. The main topics to be discussed are: the abolition of delivery systems, inspection and control in the first stage of disarmament, the spread of nuclear weapons, nuclear-free zones, the role of non-aligned nations, and the test ban and problems of detection.

Among the participants will be a dozen scientists from the United States, a dozen from the U.S.S.R. and six from the United Kingdom. Among those coming from the United States are Profs. Paul Doty, Franklin Long and I. I. Rabi; from the U.S.S.R., Academicians V. A. Kirillin, I. E. Tamm and A. N. Tupolev; and from the United Kingdom, Sir John Cockcroft and Prof. P. M. S. Blackett. As with previous Pugwash Conferences, where maximum freedom of discussion is all-important, the Conference will be private. But also, as usual, the findings of the scientists will be sent to Heads of States and other interested bodies. The host for the Conference will be the Council of Yugoslav Academies. Further information can be obtained as follows: until September 13, Prof. J. Rotblat, secretary-general of the Pugwash Continuing Committee, St. Bartholomew's Hospital Medical College, London, E.C.1; from September 13 until 18, Gerald Leach, 110 Regent's Park Road, London, N.W.1.

Announcements

The Minister of Power and the Secretary of State for Scotland have appointed Prof. A. L. L. Baker, professor of concrete structures and technology in the Imperial College of Science and Technology, London, and Mr. R. K. Christy, H.M. Chief Inspector of Factories, to be members of their Nuclear Safety Advisory Committee.

Mr. G. B. Townsend has been appointed technical manager of the Professional Television Department of the Rank Cintel Division of the Rank Organization. Mr. Townsend was formerly with the General Electric Company, having joined its Research Laboratories at Wembley in 1940, where he worked on radar and secret weapons and was afterwards responsible for the research work on television problems. In 1961 he transferred to G.E.C. (Electronics), Ltd., as manager of the new Television Equipment Department. Mr. Townsend is president of the British Amateur Television Club and chairman of the Council of the Television Society.

A meeting of the Biochemical Society will be held in Aberdeen during September 26–27. A colloquium on "The Metabolism of Protozoa" will be held during the meeting. Further information can be obtained from the Meetings Secretary, the Biochemical Society, 20 Park Crescent, London, W.1.

A conference on "The Design and Use of Microwave Valves", arranged by the Electronics Division of the Institute of Electrical Engineers, will be held at the Institute during October 16–18. Further information can be obtained from the Secretary, Institution of Electrical Engineers, Savoy Place, London, W.C.2.

The twenty-fourth national Conference for the Preservation of the Countryside, arranged by the Council for the Preservation of Rural England, will be held in Plymouth during October 10–12. Further information can be obtained from the Secretary, Council for the Preservation of Rural England, 4 Hobart Place, London, S.W.1.

The seventh conference on "Analytical Chemistry in Nuclear Technology", sponsored by the Analytical Chemistry Division of the Oak Ridge National Laboratory, will be held in Gatlinburgh, Tennessee, during October 8–10. Further information can be obtained from C. D. Susano, Oak Ridge National Laboratory, P.O. Box X, Oak Ridge, Tennessee.

An ordinary meeting of the North of England Section of the Society for Analytical Chemistry will be held in Manchester on September 28. A paper on "The Chemistry of Wines and Spirits" will be presented and discussed at the meeting. Further information can be obtained from the Society for Analytical Chemistry, 14 Belgrave Square, London, S.W.1.

The Basic Science Section of the British Ceramic Society is holding a meeting on "Point Defects in Non-Metallic Solids" at Leamington Spa during October 14–16. Registration is necessary, and further information can be obtained from Dr. J. P. Roberts (honorary section secretary), Houldsworth School of Applied Science, the University, Leeds, 2.

The fourth International Aerosol Congress and Exhibition, organized by the British Aerosol Manufacturers' Association at the invitation of the Federation of European Aerosol Associations, will be held in Brighton during October 7–12. Further information can be obtained from the Conference Secretary, International Aerosol Congress Office, Milbanke Way, Bracknell, Berks.

INDUSTRIAL RESEARCH IN BRITAIN

*RESEARCH for Industry 1962** comprises, as usual, the report of the Industrial Grants Committee, progress reports from research associations the grants of which came up for renewal in 1962 and a directory of the research associations to-day, which this year is much shortened, the lists of publications and an outline of the scope of the present work of each association being omitted. There are also two special articles: one "Bridging the Gap" by H. W. Griffith, general manager of Shirley Developments, Ltd., describes the functioning of Shirley Developments, Ltd., to illustrate the conditions to be met in any such successful venture to bridge the gap between research and the application of research results in industry; the other by Dr. D. F. Galloway, director of the Production Engineering Research Association, on sponsored projects in a research association, describes some of the sponsored projects carried out by that Association. In a third article the Industry Division of the Headquarters of the Department of Scientific and Industrial Research reviews world developments in co-operative research.

This year the work of nine research associations is reviewed. The first of these, the British Boot, Shoe and Allied Trades Research Association, serves an industry which purchases some £100 millions worth of materials and components, expenditure which the Association seeks to minimize by establishing quality targets, grades and specifications. The Association has been conspicuously successful in its contribution to the efficiency of shoe factories and management techniques, and major contributions from physics research have been made to speeding throughput and reducing the volume of work in progress by design of equipment to give appropriate physical treatment to goods in progress. For example, exposure of shoe uppers, while on the last, for a few minutes to moisture and high temperature gives a standard of 'set' superior to that given by many days on the last at room temperature: this has been applied to the design of setting machines. A process-control system developed by the Association is being operated in many factories, and examples of the Association's work are to be found in children's shoes, industrial footwear, including safety boots and shoes, in the Services' footwear and in special footwear for expeditions.

The British Ceramic Research Association refers to the increased exchange of ideas between the main research divisions and the recognition of certain areas of common interest. For example, in the examination of the extrusion of clay, undertaken primarily to establish the cause of lamination in extruded bricks, which has provided new information on the plastic behaviour of clay, and on the role of the different parts of the auger machine in determining the texture of the extruded column and in the study of moisture expansion of fired products which, with the study of fixing methods, has greatly reduced crazing of tiles in service, and has also made it possible to place the moisture expansion of building bricks in its proper perspective as a factor in building costs and maintenance. Studies on basic refractories have contributed substantially to the productivity of the steel industry, and the interest of the Special Ceramics Division has now moved to such compounds as silicon nitride, silicon carbide and boron nitride.

The Coal Tar Research Association has discovered a new method for the industrial separation of the pyridine–picoline fraction of tar bases, but a major share of its attention is now being directed to the development of new and more lucrative outlets for pitch and creosote. Besides special anti-corrosion paints, special plastic enamels for protecting underground pipelines have been developed, improved pitch/asbestos compositions, and pitch/polymer compositions for adhesives and thermoplastic mouldings. Fundamental research has included statistical structural studies on the more complex fractions of pitch and the study of the ozonolysis of polynuclear hydrocarbons; development of a simplified method for the design of continuous distillation columns and of capillary column chromatographic analysis of mixtures of low volatility.

Researches of the British Coal Utilization Research Association on the nature of deposit formation and corrosion from the combustion of pulverized fuel and the causes of corrosion of austenitic steels in the boiler furnace are expected to lead to a better understanding of conditions within a boiler furnace and how these may be controlled, so as to eliminate or alleviate availability problems. Its experience with slagging cyclone combustion led the Ministry of Power to sponsor the investigation and development of a fixed-bed slagging gasification process, eventually to work under pressure. Work on furnace practice has sought to provide specific information on the operation of producer gas-fired furnaces and kilns.

A major technical development in the hatting industry was the introduction, through the work of the British Hat and Allied Feltmakers Research Association, of a fur-felt hardening machine. Also, a system of quality control set up within the industry embodies the standardization of raw materials, and use of process controls and felt quality indexes developed by the Association, which, in the past five years, has extended its activities to hat-finishing processes. Fundamental work has included measurement of the physical properties of felt, including shock-absorbing and frictional properties, and studies of the mechanism of the fur-felting process.

Main achievements of the British Iron and Steel Research Association during the past five years include a device which applies automatic controls to the power input of electric arc furnaces and has greatly improved their efficiency and lowered their running costs; development of a pilot plant for the continuous vacuum treatment of molten steel, giving clean steels with greatly diminished hydrogen content and better fatigue properties; an experimental forging plant embodying better control systems which promotes faster and more accurate working, better utilization of plant and greater saving of labour; and a new annealing cycle and plant which offers substantial reductions in capital expenditure and lower running costs.

The British Paper and Board Industry Research Association, which increased its staff from 70 to 100 during the period and its annual income from £95,000 to £136,000, formulated a new theory for paper structure and properties as a result of a microscopic study of fibre structure and fibre-to-fibre bonding. This theory predicts that many unmeasured and as yet unconsidered properties of the structural components of paper, such as those governing shrinkage, contribute to its mechanical strength. A new method of removing water, devised by the Association, called 'fluidized-bed drying' involves passing the paper web vertically upwards through a bed of sand or glass ballotini which is continually 'fluidized' by air jets, and places have been drawn up for installing five such fluidized beds to operate in series on an experimental machine in a member's mill. A specification for pulp-baling wires, resulting from work in conjunction with the British Iron and Steel Industry Research Association, should considerably reduce the risk of accidents in hand-

* *Research for Industry 1962*: a Report on Work Done by Industrial Research Associations in the Government Scheme. Pp. iv+74+22 plates. (London: H.M.S.O., 1963.) 7*s*. net.

ling these bales by hooking under the wires, since the breakage-resisting qualities of the weaker types of wire will be increased. The Association recently published a book entitled, *A Background Course in Radiological Safety*.

One of the most important research projects of the Timber Research and Development Association has been the development of timber shell roofs, while the development of steel connectors and glues by providing efficient systems of jointing wood has reduced the main restriction to its use for large-scale construction. New systems of house building are being developed to increase the rate of house building by using standardized mass-produced factory components in wood and the Association has co-operated with the London County Council in the design of 700 mobile homes for London's homeless.

A principal technical success of the earlier work of the Water Research Association was research into the mechanism of the chemical process by which turbid waters are clarified in water-treatment plant, and this has laid the basis for a proper understanding of the process. The loss of water by leakage from distribution mains represents a probable cost to the consumer of at least £7 million a year, and an operational research investigation is being made based on such factors as the cost of inspection, the manner in which leakage falls with more frequent inspections, rate of growth of an unrepaired leak, and the increasing damage done by leak with time. Efforts are also being made to improve the technique of detection, and instruments and techniques are also being developed for the more accurate calculation of the yield of water from catchment areas and underground sources.

MANAGEMENT EDUCATION AND TRAINING NEEDS OF INDUSTRY

THE report of the Working Party of the Federation of British Industries on *Management Education and Training Needs of Industry** does not seek to suggest the precise methods by which those existing needs should be met. It seeks rather to clarify the issues, removing the confusion of aims at various levels and defining more precisely the needs of industry itself. By implication it rejects the use of the term 'business' instead of management as suggested at the Home Universities Conference last year, although the report itself restricts the use of the term 'manager' to one who practises management and not to a rank or an appointment. It distinguishes in detail between management and supervision desiderating different qualities for the two functions, and, while critical of the present products of higher education, makes little suggestion as to how this basic education should be obtained. Perhaps the most useful feature of the report is its adoption of the term 'training' rather than education for the measures required to fit the manager for his job, whether at departmental level or in general or higher management.

Postulating that the term 'management' should not be used in the designating of any courses devoted largely to supervisory aspects and that the difference between management and supervision needs to be clearly recognized in the scope of the courses and the terminology used, the Working Party recommends that the curricula in schools and universities should devote much more attention to a knowledge and understanding of the social, economic and political influences of the present time and to the underlying purposes and objections. This, of course, is a matter of the fundamental general education on which any training course for management must be built. However, in its next recommendation the Working Party loses sight of the distinction between education and training and calls for development of a progressive structure of management 'education' for the three clear stages of departmental, general and higher management, no course attempting to cover more than one stage. The first courses of approximately three months or the equivalent are recommended at post-graduate level with opportunities for experience in the practical problems and actual conditions of the chosen environment. The second residential courses of some three months are recommended at not more than one or two centres with the necessary outstanding staff and a specially designed syllabus. The needs of higher management should be met by week-end study conferences or at the most five-day seminars at a few centres where the necessary resources are concentrated. More research is recommended in specific management techniques by those universities and centres which provide management training courses. The courses themselves would benefit and a consultancy service could emerge; but this needs the full support of industry. Training for management must proceed side by side with education, and opportunities must be provided within the organization for progressive instruction and practice in responsibility through staging posts and under senior guidance. In all this there must be the closest link between educational institutions and industry. A critical review of the needs should be the basis of the courses provided and opportunities afforded for the demonstration of principles and observation of practice within industry itself.

VETERINARY SCIENCE AT BRISBANE

THE Colin Wright Tropical Preventive Medicine Laboratory at the Veterinary School Farm, Brisbane, was built with funds from a variety of sources, which included a donation from the Beneficiaries of the Wright Estate, Imperial Chemical Industries of Australia and New Zealand, Ltd., the Australian Cattle and Beef Research Fund, and the Wool Research Fund.

The nieces and nephews of Mr. Colin Wright of 'Waverley', St. Lawrence, intended the Laboratory "to be a memorial of his work, which illustrated that the introduction of Brahman blood into beef cattle herds in the Tropical Coast is a profitable commercial proposition". It is of interest that Waverley Station, which is some 160 miles north of Rockhampton, adjoins the Cattle Station on which Mr. Christian developed the formula of his arsenical dip for cattle ticks in 1895; this formula was used throughout the world with only minor modification for the next fifty years.

Work on the Farm over the past five or six years has shown that the presence of, say, forty engorged ticks on a young bovine will reduce its growth at the rate of approximately 40 lb per annum[1].

The herd of Droughtmaster cattle on the Farm has carried about ten times fewer ticks than British cattle grazed with them, and the Droughtmasters have never had to be dipped or sprayed[2]. Droughtmasters are a

breed similar to the Santa Gertrudis produced by crossing Brahman and British beef cattle. They are approximately half Brahman compared with the three-eighths of the Santa Gertrudis. The importance of this is difficult to overestimate: there are a few British cattle with quite high tick-resistance, but it would obviously take a long time to raise the overall tick-resistance to a high level. On the other hand, one cross with a Brahman bull raises tick-resistance about ten-fold, and we can still select for tick-resistance. These facts were well understood by Dr. R. B. Kelley, who contributed so much in this field, and they have, in fact, been well established, even if their importance has not been well or widely accepted, for at least forty years. Unfortunately, for a long time the subject of 'tick-resistance' seems to have caused considerable confusion in the minds of people regarded as experts on ticks, or at least they have not appreciated its importance. However, a few people have had a clear understanding, and a paper published early in this century described how pastures grazed by tick-resistant cattle were steadily 'cleansed' of ticks. The Droughtmasters and Brahman-hybrid cattle are also considerably more resistant to babesiosis[3] than European cattle.

The Farm, of some 700 acres, is only seven miles from the new Veterinary School at St. Lucia which was opened in August 1961 by the Hon. C. F. Adermann, Minister for Primary Industry. There are now almost 100 students in each of the first two years of this school, and 36 post-graduate students.

AUSTRALIAN DEFENCE STANDARDS LABORATORIES

THE main sections of the illustrated annual report of the Department of Supply of the Australian Defence Standards Laboratories for the year ended June 30, 1962, deal with the work carried out in the fields of physics, metallurgy and chemistry.

The Physics Division consists of the metrology, electronics, electrical measurements, chemical physics and optics, and xerography groups and branches in New South Wales and in South Australia. The two items of special interest in the Division's activities during the year are the production of calibration tables for platinum resistance thermometers by means of an IBM 1620 digital computer and the acquisition of one of the highest precision Mueller resistance thermometer bridges yet built.

The bridge, which incorporates all the latest developments and modifications from the United States National Bureau of Standards, has nine dials covering the range 0–422 ohms in increments of microhms. The Division's 'Varian' wide-line nuclear magnetic resonance spectrometer was used in the study of a number of chemical and physical problems, including the determination of the separation between hydrogen atoms in the water of crystallization in calcium sulphate hemihydrate and the observation of some nitrogen, zinc and chromium resonances. The resonance of the tin-119 isotope, which is of low natural abundance and of relatively poor sensitivity, was recorded in a series of liquid tributyl tin compounds of particular interest in the development of plastics resistant to corrosion and to penetration by fungi. The shift of the tin resonance in each molecule relative to the resonance of the stannous ion was measured and explained on the basis of simplified models.

Mention was made in the 1961 annual report of investigations on the vaporization processes occurring on the surfaces of metal electrodes when subjected to low-current long-duration pulsed discharges. These have been continued. In the field of solid-state physics small-scale experimental work was started on hot carrier conduction in silicon. In the metrology group a method was devised for the use of the 'Talyrond' roundness measuring instrument for the accurate measurement of standard ring gauges, and an experimental mercury manometer of 5-cm bore was constructed for the measurement of pressures of 0–60 millibars to an accuracy of 10^{-2} millibar.

The Metallurgy Division was mainly concerned with the production of pure chromium and with the study of the properties of chromium and chromium alloys. In collaboration with Dr. P. A. Jacquet a new technique was developed for the preparation of chromium for microscopic examination with either the optical or electron microscope. Internal friction studies established that the extent of magneto-mechanical damping and associated hysteresis in chromium is markedly dependent on grain size and on impurity content. Measurements of the dynamic shear modulus of chromium at 1 c/s over the temperature-range $-100°$ C to $100°$ C showed that the modulus has a maximum value at the antiferromagnetic transition temperature (Néel temperature). The metallographic study during 1961 of abraded germanium surfaces led to the surprising result that the damaged layer consisted of cracks and not of large densities of dislocations. This work was extended during 1962 to the examination by microscopy and by taper-sectioning techniques of the extent to which the damage is removed by etching with '*CP*-4' reagent. It was found that the reagent penetrated the cracks and opened them into broad crevices, but that at the same time the surface was smoothed out with the production of a characteristic cellular pattern. The damage in electric spark-machined surfaces was also studied.

Some interesting results were obtained from the structural studies and stereochemistry investigations in the Chemistry Division of the aliphatic cyanides and isocyanides which, despite identical molecular formulæ, differ considerably in chemical and physiological activity. The contribution of the isocyanide bond to the molecular refraction is much greater than that of the cyanide bond, and the effects of hydrogen-bonding solvents on the infrared spectra of the two families of organic compounds and of carbonyl compounds differ markedly. Other activities in the Chemistry Division include the determination of gases in metals, in particular oxygen in chromium by the vacuum fusion and the Adcock chemical methods, and phosphorus in irons and steels using quinoline molybdate instead of the more usual ammonium molybdate, and X-ray fluorescence analysis of the ternary alloys Fe-Cr-Ni, Cu-Ni-Zn and Cu-Zn-Sn.

The annual report lists the various personnel of the Laboratories and their status, and gives details of the publications by members of the staff during the year under review. The staff numbered 724 on June 30, 1962—an increase of 37 during the year, reflecting the somewhat easier position in the recruitment to sub-professional positions. Nine members of the staff spent all or part of the year in the United Kingdom. Visitors to the Laboratories included the Australian Minister for Supply; Prof. K. H. Hunt of Monash University; Prof. S. Kikuchi of Tokyo University; Sir Leslie Martin, chairman of the Australian Defence Research and Development Policy Committee; Dr. P. Cheosakal of the National Research Council of Thailand; Dr. W. J. Youden of the United States National Bureau of Standards; and a party of sixty officers from the Australian Army Staff College.

S. WEINTROUB

NORWEGIAN GLACIERS

GLACIOLOGICAL research at the present time consists of two main tasks: first, the recording of the state and behaviour of glaciers; and secondly, the study of the various factors controlling their behaviour. The latter normally progresses by intensive studies in limited areas or of specific problems. The general recording of glaciers and their behaviour requires widespread survey, mapping and a continued interest in glaciers and the surrounding country spread over many years. Adolf Hoel and the late Werner Werenskiold have had both broad and specific interests in the glaciers of Norway throughout their lives. In the *Glaciological Bibliography of Norway* * entries under Adolf Hoel are dated from 1906–56, and under Werner Werenskiold from 1913–61. Their lifetime interest and knowledge of Norwegian glaciers makes their general review of *Glaciers and Snowfields in Norway* † a work of authority and value. It is written in English, and will thus be useful to students in many countries.

The first section of *Glaciers and Snowfields in Norway* deals with the history of glaciological research in Norway, then lists the glaciers of Norway with details of their area. Dates of surveys are given, since it has not been possible to survey all glaciers contemporaneously. Data for southern Norway are mostly up to date (about 960 glaciers), but in northern Norway many surveys used were made around the beginning of this century, since when a marked recession may have decreased the area of glaciers by perhaps 30 per cent. However, dates are given and changes to the present day can be determined by field parties visiting these areas. The present senior glaciologist of the Norsk Polarinstitutt, Olav Liestol, has always been a ready guide and helper to those seeking advice on where mapping of the glaciers will be most useful, and this volume may stimulate further work.

Former glacier fluctuations are discussed in the light of indirect evidence, such as the preservation of arrowheads and ropes by ice, which indicates that snow and ice cover must have increased from at least A.D. 1500 until A.D. 1750, when a general recession commenced. Although some advance occurred in the period 1850–55, it appears less marked than that in the European Alps. Spitsbergen glaciers are also discussed, where, apart from a general decrease in size in recent decades, some catastrophic advances, such as that which added 600 km² to the area of Bråsvelbreen, are noted.

The section discussing benefits derived from glaciers starts naturally with their relations to hydroelectric power. Glaciers also provide useful lines of communication of use between settlements as well as by tourists. Commercial exploitation of glacier ice is also covered. Collection by fishing vessels for refrigeration purposes was important for at least thirty years up to 1949 near Oksfordjokulln, but other forms of export of ice, although pursued, were apparently less successful in this area.

The remaining 170 pages of the book presents a wealth of data on glaciers studied by Hoel, Werenskiold and their associated workers. Work in the Jotunheim area over the period 1927–48 covers surveys, accumulation, ablation, velocity, stream discharge and other measurements. Studies have concentrated especially on Hellstugubreen and Tverråbreen. Maps of both glaciers and a series of maps of Tverråbreen during 1927–38 are presented in a separate folder. Similar investigations on glaciers in northern Norway are presented.

The *Glaciological Bibliography of Norway* contains some 1,500 references to work on Norwegian glaciers presented both as a regional and as a chronological (author) catalogue. Its usefulness is increased by symbols denoting that the papers contain maps or photographs of special use for future comparisons. References are cited up to 1958 with some additions to 1961.

All those interested in the study of Norwegian glaciers will benefit greatly by these publications, which not only draw together a considerable amount of scattered work, but also contain many sections which would interest anyone visiting these areas. G. DE Q. ROBIN

FORAGING AND FEEDING BEHAVIOUR

A SYMPOSIUM of the Society for the Study of Animal Behaviour held at the London Zoological Gardens during July 9–11 was devoted to the topic of "Foraging and Feeding Behaviour". Most of the papers read on the first day of the meeting dealt with insects and had an ecological rather than ethological flavour. F. Raw (Rothamsted Experimental Station) was more concerned with the aspects and effects of foliage disposal by earthworms than with the behavioural mechanisms operative in this remarkable affair, interest in which goes back to Darwin. "As fallen foliage in orchards harbours stages in the life-cycle of fruit tree pests its speedy disposal is an important factor in the health of the fruit trees." Leaf burial by earthworms (*Lumbricus terrestris*) is, therefore, of great potential ecological importance.

Barbara A. Hopkins (Ascot Field Station of the Imperial College of Science and Technology) reported on the "Probing Response of *Stomoxys calcitrans* (the Stable Fly) to Odours". Ammonia chiefly and a series of other components were offered to individual flies after and during a 24-h period following a blood or sugar meal, and their proboscal probing was observed. Probing does not seem to be associated with need for water and shows no obvious 24 h or longer period rhythmicity. Its threshold also is unaffected by larval environment or crowding. This gradually fell during the 24 h after feeding. There is some evidence that receptors responsible for the probing sequence are located on the tarsi. *N*-propyl amine and several lower fatty acids approach ammonia in stimulating effect. A. J. Cockbain (Rothamsted) also dealt with probing in his paper on "The Probing and Feeding Behaviour of Alate Aphids in Relation to the Transmission of Some Plant Viruses". He showed that infectivity with non-persistent viruses such as pea and sugar beet mosaic virus is associated with short duration probing and not with prolonged feeding on infected plants. Many *Myzus persicae* individuals but few *Aphis fabae* probe for a short time (15–60 sec) before flying from infected plants on which they have been feeding. This may explain the difference in infectivity of the two species. *A. fabae* also seem to fail to insert their stylets into the plant tissues when probing.

"The Feeding and Excretion Behaviour of Aphids" was analysed quantitatively by C. J. Banks (Rothamsted). He demonstrated that most aphids feed on the phloem tissues of the host plant. That they feed on the sieve tube elements has only rarely been convincingly demonstrated. It may take them as long as 14–16 h to reach the maximum rate of feeding. In this aphids do not seem to rely entirely on the sap pressures within the plant and there is some evidence for active sucking and relation of intake to need during post-reproductive ageing when excretion has stopped.

J. Sudd (Department of Zoology, Hull) analysed the behaviour involved in the transport of prey by ants and finds two chief mechanisms: namely, dragging and pulling. Successful dragging presupposes visual orientation as it involves reversal of the ant's alignment with respect to the homing direction. Pulling is compatible with preponderantly olfactory and tactile tracking. In *Formica lugubris* disordered movement by a number of collaborating ants is followed by a pause of several minutes before rapid and orderly concerted movement towards the nest occurs. The middle pause of no movement seems to be a state of equilibrium.

J. B. Free (Rothamsted) returned to the orchard with a study on "The Foraging of Honeybees in Fruit Orchards" and showed that nectar gatherers, especially those that stand on the petals, do not touch the stigma and thus fail to pollinate although they may receive pollen from flowers with spreading stamens such as apricot, peach, pear and plum. On some apple varieties with stiff, upright stamens no pollen is transferred to the nectar gatherer. Feeding with sugar syrup switches a greater proportion of foragers to pollen collecting and thus increases the chances of successful pollination. Bees keep to a row of trees and change to trees nearest to those initially collected from. This is of importance for maximum fruit set in trees needing cross-pollination and points to an optimal pattern of arrangement of varieties in apple orchards. As bees tend to forage near their homes, especially in unfavourable weather, colonies should be sited in small groups each near the centre of the area to be pollinated. Colonies should not be taken to the orchard until flowering has begun, as bees will not readily change to the fruit blossoms after having collected from other plants.

The rest of the first day was devoted to lower vertebrates. L. de Ruiter (Zoology Laboratory, Groningen) gave a paper on "The Feeding and Foraging in the Stickleback: Causes and Consequences" in which he demonstrated the factors involving visual feeding under quantitatively controlled conditions, and J. S. Kenny (Department of Zoology, Birkbeck College, London) gave an account of "A Typical Use of the Ciliary Feeding Mechanism in Some Anuran Larvæ" in various ecological niches. The primary feeding mechanism involves the buccal rasp, filters and mucus string aggregation and transport of particles by ciliary action. Mid-water and surface-feeders may show modification in the primary mechanism such as increase in filtering area and loss of the buccal rasp. Secondary adaptations of tail and lips were also described.

The second day of the symposium, devoted entirely to bird behaviour, opened with a paper by P. M. Driver (Department of Extra-Mural Studies, Bristol) on "The Development of Feeding Mechanisms in *Mergini*", followed by an account by Janet Kear (The Wild Fowl Trust, Slimbridge) on the "Parental Feeding Behaviour in the *Anatidae*". True ducks scarcely ever feed their young, but in *Anseranas*, *Dendrocygna* and *Cygnus* parental feeding is well established. The development of parental feeding may start with the young feeding on surplus food falling from the bill of the parent. This is supported by innate pecking upwards of newly hatched anatids towards the tip of pointed objects, including the bills of siblings and parents. In the magpie goose, begging and the brightly coloured head of the goslings act as releasers for parental feeding. "The Feeding Behaviour of the Wood-pigeon" was analysed by R. K. Murton (Field Research Laboratory, Worplesdon, Surrey). When food supplies are limited *Columba palumbus* feeds gregariously and 95 per cent of the food is made up of clover leaves. The birds feed almost continuously and selectively. The importance of a 'specific search image' was demonstrated. The speed of searching is correlated with food density. The prime function of flocking is to maintain a maximum population size where random distribution of birds without competition leads to excessive mortality.

D. J. McFerland (Institute of Experimental Psychology, Oxford) reported on "Some Interactions of Feeding and Drinking Behaviour in the Barbary Dove". These birds eat less when thirsty and drink less when hungry. This was held to be the consequence of an antagonism between the hypothalamic feeding and drinking systems. In a Skinner box thirsty birds go on working for food but do not eat it (displacement feeding ?). It appears that the food deficiency incurred in thirsty doves is capable of activating the relevant appetitive behaviour despite the fact that the birds are unable to eat the food which they obtain in this way.

In the afternoon those attending the symposium were given an opportunity to visit the Zoo and the Granada Television Film Unit and to see there a preview of unedited film material, including a fascinating close-up colour film of cobbler ants at work building their nests from leaves sewn together with the silk produced from the silk glands of their larvæ.

In a paper not originally included in the programme of the third (day which was devoted to mammalian behaviour) J. A. Chmurzyński (Nencki Institute of Experimental Biology, Warsaw) described "The Stages in the Spatial Orientation of the Digger Wasp, *Bembex rostrata* L.". There are three stages of spatial orientation: distant orientation outside and within the life-range (about ½ km from the nest) with random and chiefly visual orientation respectively; proximal orientation (about 4 m from the nest depending on frequency and distinctiveness of natural landmarks—here visual and olfactory senses guide the orientation and recognition; "immediate orientation" (not more than 6 cm from the nest) when the insect finds the nest by making use chiefly of tactile clues. Three papers on various aspects of feeding in ruminants by A. Brownlee (Agricultural Research Council Institute for Research on Animal Diseases, Compton, Newbury), C. C. Balch and R. C. Campling (National Institute for Research in Dairying, Shinfield, Reading) and D. T. Chambers (Grassland Research Institute, Hurley) dealt with rumen development as related to food regimen, with the rate of eating and relative length of periods of ruminating in relation to different kinds of food, and with selective grazing habits of cattle and the associated problem of wastage respectively. A. J. B. Rudge (Infestation Control Laboratory, Guildford) reported on a preliminary investigation into baiting of wild rabbits. Whole carrots were shown to be a most suitable form of unpoisoned bait. P. R. Wiepkema (Zoological Laboratory, Groningen) spoke on the physiological significance of feeding-patterns in mice. Hyperphagia, aphagia and finickiness are considered in their relation to lesions in the ventro-median nucleus of the hypothalmus. Perception of food quality activates a hunger system which in turn stimulates a motoric eating centre. After food uptake three negative feed-back channels can be distinguished, namely, a stomach factor, a blood glucose factor and a body-fat factor. They sum up into a satiety system which inhibits the hunger system. The probable effects of ventro-median lesions on these feed-back systems were discussed.

"The Ethology of Food Hoarding in Mammals" was discussed by M. Lyall-Watson (Zoological Society of London). He gave a comprehensive survey of the different methods utilized by mammals in accumulating stores of food. Larder hoarding and scatter hoarding can be distinguished and related to seasonal requirements and

types of food. The scatter hoarding in South American green acouchi, *Myoprocta pratti*, was subjected to a closer ethological analysis.

The symposium closed with an analysis of "The Aetiology of Food Reward in Monkeys" by L. Weiskrantz (Psychological Laboratory, Cambridge) and a paper on "Chimpanzee Behaviour in Relation to the Predominant Food Sources" in which V. Reynolds (London) described the overall pattern of chimpanzee activity as an alternation between convergence on areas with plentiful food and scattering when food is scarcer. This lead to optimal exploitation. The loose social structure of chimpanzees who live in bands of ever-changing size and composition may be considered to be an adaptation to the type of food distribution.

The topics discussed at this symposium clearly belonged to the borderland between ecology, horticulture, husbandry, physiology and ethology, and, although behavioural aspects were frequently not in the foreground, the meeting served the useful purpose of cross-fertilization during lively and informative discussions.

O. Lowenstein

IONOSPHERIC EFFECTS DUE TO THE EARTH'S ORBITAL POSITION

By Dr. G. NOCI
Osservatorio Astrofisico di Arcetri, Florence, Italy

In the article by Sir Edward Appleton on "Ionospheric Consequences of the Earth's Orbital Eccentricity"[1] it was shown how the peak electrons number present in 1 cm³ of the E ionospheric layer ($N_m(E)$) changes during the year according to the variation of the distance of the Earth from the Sun. In Fig. 1 of Appleton's article (Fig. 1(a) of this paper) is shown a graph obtained by working on the results of ionospheric soundings performed during 1949–59 by several stations and leaving out all effects due to the variation of the solar activity (R) and to the variation of the zenithal distance (χ) in the places of observations; on the whole this result must be considered valid for R = constant and $\chi = 0$.

Going from the perihelion to the aphelion, that is from the beginning of January towards the beginning of July, the distance between Earth and Sun (r) changes of 3·4 per cent; this means a variation of the solar flux of 6·5 per cent during this interval. Such value is in good agreement with the experimental one shown in Fig. 1 of Appleton's article if we assume the electronic density ($N_m(E)$) proportional to the flux of the ionizing radiation (q) (electrons loss described by an attachment law). There is still a difference of 1 per cent between the variation of q and that of $N_m(E)$ to be explained: according to Appleton this is due to an unknown cause.

In this article I would like to show how the discrepancy between theoretical values and results is not only due to this difference—even in the hypothesis of an attachment law for the electrons—and to explain its cause.

In the curve of Appleton's Fig. 1 the width of the concavity is too small compared with the curve showing the behaviour of $1/r^2$: in fact, if 'a' is the length of the major semi-axis of the Earth orbit, it can be easily seen

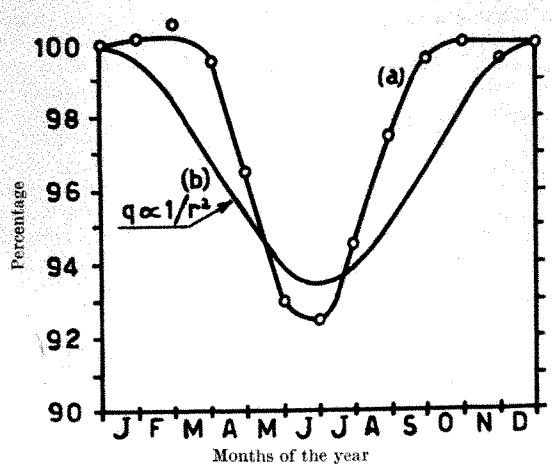

Fig. 1. Comparison between $Nm(E)$ (curve a) and the solar flux supposed proportional to $1/r^2$ (curve b)

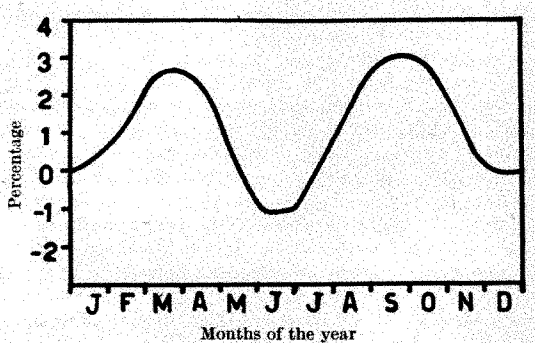

Fig. 2. Difference between the curves (a) and (b) of Fig. 1; that is, annual variation of the E layer electron concentration due to that part of the ionizing flux which is not proportional to r^{-2}

that the average between the upper and the lower limits of the function $1/r^2$ is larger than $1/a^2$. Besides, the arc of the ellipse made by the Earth from the perihelion to the instant in which $r = a$ (and naturally $1/r^2 = 1/a^2$) is equal—for well-known properties of the ellipse—to a

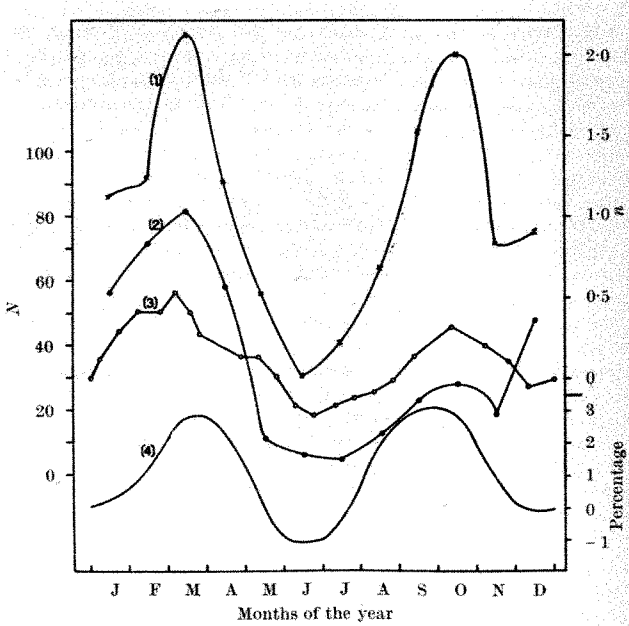

Fig. 3. (1) Annual variation of the number of nights with auroræ in Denmark (ref. 2) during 1897–1937 (scale on the right top). (2) Annual variation of the number of nights with zodiacal light (ref. 3) during 1847–1875, according to Heis (scale on the left). (3) Annual variation of the number of magnetic perturbations in Paris (ref. 4) during 1883–1923 (scale on the left). (4) Annual variation of the 'residual' peak electron concentration in the E layer (that is, the curve of Fig. 2) (scale on the right, below)

quarter of the ellipse total length. Let us consider now the time needed by the Earth to make that part of the ellipse are going from the point where $r = a$ to the symmetric point passing through the aphelion. For the second Kepler's law this time is more than that needed to make the complementary arc; it is now clear that the width at half depth (that is to a level higher than $1/a^2$) of the concavity of Appleton's Fig. 1 should be larger than six months if such curve is to behave according to $1/r^2$. This width is instead much smaller.

However, the curve showing the behaviour of $N_m(E)$ has another important characteristic, besides being too deep, which cannot be simply explained by the variation of the distance Earth–Sun. This can be seen in Fig. 1 of this article where the curve (a) is compared with the graph of $1/r^2$ (b); in Fig. 2 the difference (a) – (b) is made evident.

Particularly interesting is the graph of Fig. 2 which can be considered as showing the temporary behaviour of that electrons number fraction (as a percentage of the maximum value) which is not explained by the simple model $N_m(E) \propto q \propto 1/r^2$. Obviously this fraction contains an undefined additive constant and therefore the position of the zero in Fig. 2 is arbitrary.

It can now be seen that the phenomenon showed by such a curve is much more complicated than being a simple excess in the reduction of the electronic concentration in June. Nevertheless from this new characteristic I am now able to suggest the origin of this effect. In fact some other phenomena show seasonal variations of this type, with maxima around the equinoxes and minima around the solstices: between such phenomena there are: aurora polaris[2], zodiacal light[3] and geomagnetic perturbations[4] (Fig. 3). (Note that the increase of electron density in the E layer during magnetic storms is proved.) Their behaviour seems due[5] to the fact that near solstices (that is, at the beginning of June and December) the Earth passes through the plane of the solar equator, and therefore it faces a solar region of low activity. Vice versa in March and September the radius Earth–Sun is nearest to the region of medium latitude—north or south—where the sunspots are present. From these regions a corpuscular radiation, responsible for phenomena of this type, should be emitted. In other words, the Wolf relative number R has a different weight when the Earth faces a solar region in which there are spots or when the Earth faces a less-active equatorial region.

It is to be noticed that the remarked greater depth of the curve in June compared with December is a characteristic common to all mentioned phenomena (Fig. 3).

Furthermore I must emphasize that a curve similar to that of Fig 2 is also obtained if one supposes the electron loss in the E region described by a recombination law ($N_m(E) \propto q^{1/2}$) or by an intermediate law ($N_m(E) \propto q^n$; $0{\cdot}5 < n < 1$).

RED CELL ACID PHOSPHATASE VARIANTS: A NEW HUMAN POLYMORPHISM

By Dr. D. A. HOPKINSON, Dr. N. SPENCER and Prof. H. HARRIS

Medical Research Council Human Biochemical Genetics Research Unit, and Department of Biochemistry, King's College, London, W.C.2

WHEN human red cell hæmolysates are examined by starch-gel electrophoresis, more than one zone of acid phosphatase activity is observed. Furthermore, the pattern of these zones may differ from person to person. So far we have been able to distinguish five distinct red cell acid phosphatase patterns and they appear to be characteristic for the individual and to be genetically determined.

These electrophoretic patterns may be identified by the following procedure. Hæmolysates are prepared by the addition of 2 volumes of distilled water to 1 volume of washed red cells. Horizontal starch-gel electrophoresis is then carried out at *p*H 6·0 (gel buffer: 0·005 M succinic acid and 0·0092 M *tris*, bridge buffer: 0·41 M citric acid/sodium hydroxide *p*H 6·0) using very thick filter paper inserts (Whatman No. 17). Electrophoresis is performed for 17 h with a potential gradient of 6 V/cm. in a cold room at +5° C. After electrophoresis the gels are sliced horizontally and placed in 'Perspex' boxes which have lids. The cut surfaces are then covered with a solution of 0·005 M phenolphthalein diphosphate sodium salt in 0·05 M citrate buffer *p*H 6·0 and incubated for 3 h at 37° C. After this the reagent is poured off, and a few drops of ammonia solution (s.g. 0·88) are added to the box which is then re-covered. The ammoniacal atmosphere makes the surface of the gel alkaline, and the areas where phenolphthalein has been liberated from the phenolphthalein phosphate by acid phosphatase appear as red zones. The phenolphthalein slowly diffuses so that sharp definition of the various zones only persists for about half an hour. The zones of activity may also be observed using *p*-nitrophenyl phosphate as substrate instead of phenolphthalein phosphate. However, the *p*-nitrophenol formed diffuses very much more rapidly than does the phenolphthalein and the zones are therefore much less clearly defined. We have been unable to detect these zones using α- or β-naphthyl phosphate as substrate with an appropriate diazo reagent to couple with any α- or β-naphthol liberated. This is presumably a consequence of the peculiar pattern of substrate specificity of the red cell acid phosphatase, because certain other human acid phosphatases can be readily detected with these substrates under the foregoing conditions.

Fig. 1 shows typical examples of the five different patterns of activity so far distinguished in different individuals. These types will be referred to as *A*, *BA*, *B*, *CA* and *CB*. They can be approximately described, as indicated in Table 1, in terms of the relative activity of three zones, 'fast', 'intermediate', and 'slow', which migrate towards the anode in that order. In type *A* the 'fast' zone is generally clearly defined and well separated from the 'intermediate' zone. In type *BA*, however, the 'fast' zone is less sharply defined and appears as a smear running forward from the 'intermediate' zone, which is in this type very much more intense than in type *A*. A pattern very similar to that observed in type *BA* can be obtained by the electrophoresis of a mixture of hæmolysates of type *A* and type *B* in roughly equal amounts. Types *CA* and *CB* are characterized by the presence of a very intense 'slow' zone. In type *CA* this is associated with both 'fast' and 'intermediate' zones similar to those observed in type *A* and very much less intense than the

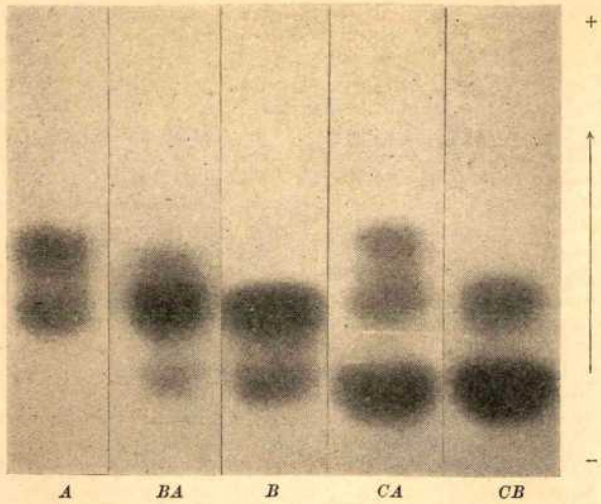

Fig. 1. Five red cell acid phosphatase patterns which may be seen after starch gel electrophoresis of hæmolysates from different individuals. The lower edge of the photograph is the start line. The hæmoglobin moves towards the cathode and is not shown

'slow' zone. In type *CB* it is associated with an 'intermediate' zone similar to that observed in type *B* and significantly less intense than the 'slow' zone. It must be noted that a distinct 'slow' zone is also observed in type *B*, but this is relatively less intense than the 'intermediate' zone in this type, and is also much less intense than the 'slow' zones observed in types *CA* and *CB*. A very weak 'slow' zone can also be regularly observed in type *BA*. In some experiments it appeared as if a faint trace of such a 'slow' zone was also present in some samples of type *A*, but this has not been observed consistently.

Despite the complexity of the patterns there is in practice little difficulty in classifying individual hæmolysates, particularly when these are fresh. Storage at +4° C and especially at −10° C results in a progressive fall in activity, and also often in some modification of the pattern, with the frequent appearance of one or more zones moving even more rapidly than the 'fast' zone referred to previously. The activity of stored samples is maintained somewhat better if 2-mercaptoethanol (1 µl. per ml. hæmolysate) is added before storage. Using this we can generally get satisfactory electrophoretic patterns up to about ten days after the hæmolysate was originally prepared.

Table 1. Approximate Description of the Five Red Cell Acid Phosphatase Electrophoretic Patterns

Zone of enzymatic activity	Red cell acid phosphatase type				
	A	*BA*	*B*	*CA*	*CB*
'Fast'	+	+	−	+	−
'Intermediate'	+	++	+++	+	++
'Slow'	−	trace	++	++++	++++

As a routine both in the frequency studies and in the family studies described later, both surfaces of the sliced gels have been classified independently by two observers. In many instances the hæmolysate has also been subjected to electrophoresis on more than one occasion. Furthermore, in a number of cases more than one sample obtained on different occasions from given individuals has been examined. In general, the classifications have been unambiguous and in agreement.

It has been shown that red cell acid phosphatase activity can be inhibited by formalin[1] but is relatively unaffected by D(+)-tartrate[2], and these characteristics have been used to distinguish this kind of acid phosphatase activity from that found in certain other tissues (for example, prostate). We have observed that if formalin is added to the reaction mixture, described, to a final concentration of 0·5 per cent, no zones of activity in any of the five types are visible after the usual 3 h incubation. On the other hand D(+)-tartrate (0·03 M in the final reaction mixture) produces no obvious change in the patterns observed. Previous evidence indicating heterogeneity of red cell acid phosphatase has been obtained from the study of *p*H activity curves[3], and from elution patterns obtained by chromatography on DEAE cellulose[4]. It is not at present clear in what way these findings are related to the variations described here.

Table 2. Incidence of the Red Cell Acid Phosphatase Types in Randomly Selected English Males and Females

Type	Males	Females	Total	Frequency
A	10	4	14	0·101
BA	50	14	64	0·460
B	33	15	48	0·345
CA	2	3	5	0·036
CB	6	2	8	0·058
Total	101	38	139	1·000

Red cell hæmolysates from 139 unrelated English people of both sexes have been examined, and the classifications obtained are given in Table 2. Since no gross sex differences in the frequencies of the various types were observed, the data for the two sexes have been combined to obtain estimates of population frequencies.

Studies have been carried out on 42 families, in each of which blood samples were obtained from both parents and one or more of their children. The results are summarized in Table 3. The families do not represent an entirely random sample, because in the early stages of the investigation we were especially concerned to study families in which the less-common types *A*, *CA* and *CB* occurred. It is apparent that the distribution of the types among the children of particular sorts of mating is non-random. Thus it may be noted that all the 16 children of the matings between parents both of whom were of type *B*, were also type *B*. Also all the children of types *CA* and *CB* observed were derived from matings in which at least one parent was also type *CA* or *CB*. In the single family of mating type *A* × *B*, all 4 children were type *BA*.

Although the family data are still rather scanty, it is perhaps useful at this stage to consider how they might be accounted for in genetical terms. One hypothesis which is consistent with the present data is the following. We suppose that the variations observed are determined by three allelic autosomal genes P^A, P^B and P^C, and that the various possible genotypes correspond to the phenotypes observed in the manner shown in the first two columns of Table 4. It will be noted that this hypothesis predicts the occurrence of a sixth phenotype, *C*, which has not as yet been observed. This phenotype, as will be shown later, would be expected to be much less frequent than any of the other phenotypes.

With six genotypes, twenty-one parental combinations have to be considered, assuming that reciprocal matings produce the same results. Many of these combinations would, of course, be relatively uncommon and in the 42 families so far studied only eleven of them have been observed. The particular phenotypes expected among the children of these matings can be readily determined, and it will be seen from Table 3 that, among the 86 children so far investigated, only the phenotypes predicted by the hypothesis actually occurred. The data are also consistent with the expected Mendelian ratios after allowance has

Table 3. Distribution of Red Cell Acid Phosphatase Phenotypes Among the Children of 11 Different Parental Combinations

Type of mating	No. of families	Children				
		A	*BA*	*B*	*CA*	*CB*
A × *BA*	5	6	5	—	—	—
BA × *BA*	10	4	12	2	—	—
A × *B*	1	—	4	—	—	—
BA × *B*	10	—	10	7	—	—
B × *B*	6	—	—	16	—	—
A × *CA*	1	—	—	—	2	—

B × *CB*	1	—	—	1	—	1
Totals	42	11	34	26	7	8

been made for the way in which the different families were selected, but larger numbers will clearly be required to test this aspect of the hypothesis adequately.

If the hypothesis is correct then estimates of the gene frequencies p, q and r of the three alleles P^A, P^B and P^C can be obtained from the frequency of the various phenotypes in the general population, in the following manner: p = [frequency of type A] + ½[frequency of type BA] + ½[frequency of type CA]; q = [frequency of type B] + ½[frequency of type BA] + ½[frequency of type CB]; r = [frequency of predicted type C] + ½[frequency of type CA] + ½[frequency of type CB]. Using the results given in Table 2, which are effectively random, the values for the gene frequencies are: $p = 0{\cdot}349$; $q = 0{\cdot}604$; and $r = 0{\cdot}047$.

From these estimates one can determine the expected frequencies of the various phenotypes from the expansion $(p + q + r)^2$ assuming random mating and the absence of appreciable selection. These can be compared with the observed frequencies. The appropriate calculations are given in Table 4. There is good agreement between the observed numbers of individuals of the different phenotypes and the numbers expected. This provides further evidence in favour of the hypothesis.

The calculations given in Table 4 suggest that the predicted but not yet observed phenotype C may be expected to occur in about 1 in 400 randomly selected individuals in an English population. One would imagine that such individuals would show a red cell acid phosphatase pattern in which there was no 'fast' zone, a very weak or perhaps absent 'intermediate' zone, and a very prominent 'slow' zone which would account for nearly all the activity present.

A number of other observations about these variations may be briefly mentioned. (1) Studies on the red cells from cord bloods have revealed patterns not obviously different from those seen in adults. Out of 12 cord bloods examined 2 were of type A, 6 of type BA and 4 of type B. (2) Inspection of the gels suggests that the overall acid phosphatase activity varies from type to type. Preliminary studies in which the enzyme activity has been assayed by standard procedures using p-nitrophenyl-phosphate as the substrate, suggest that the relative activities are $A < BA < B \sim CA < CB$. (3) In much of the family and population data reported here typing for blood group antigens, haptoglobins and transferrins, has been carried out. No obvious associations between any of these markers and the red cell acid phosphatase variants have been noted. Detailed linkage analyses have not yet been performed.

Table 4. Observed and Expected Numbers of Different Phenotypes Assuming Random Mating

Genotype	Phenotype	Expected frequency		Expected numbers in sample in Table 2	Observed numbers in sample in Table 2
P^AP^A	A	p^2	0·1218	16·9	14
P^AP^B	BA	$2pq$	0·4215	58·6	64
P^BP^B	B	q^2	0·3648	50·7	48
P^AP^C	CA	$2pr$	0·0328	4·6	5
P^BP^C	CB	$2qr$	0·0568	7·9	8
P^CP^C	[C]	r^2	0·0022	0·3	0
Total			0·9999	139·0	139

Further collection of family and population data of the sort described here should show whether the simple genetical hypothesis which we have put forward is correct, or whether some more complex explanation is required. It should also indicate whether the predicted phenotype C actually exists.

We thank Dr. M. Glen-Bott for her help with the family studies, Dr. T. E. Cleghorn for determining the blood groups, and Dr. E. B. Robson for determining the haptoglobins and transferrins.

Note added in proof. Improved separations are obtained by halving the concentration of the gel buffer. The zones of type A are then retarded so that the faster zone is ahead of and the slower zone is slightly behind the main zone of type B.

EFFECT OF INSTANTANEOUS FLASHES ON ADAPTATION OF THE EYE

Dark Adaptation after Exposing the Eye to an Instantaneous Flash

FLASH bleaching. Rhodopsin consists of the protein opsin combined with the 11-*cis* form of retinene. The primary effect of light is to isomerize retinene, and since the all-*trans* combination is unstable at room (or body) temperature it becomes dissociated from the opsin and results in a change in spectral absorption called 'bleaching'. The dissociation is irreversible, thus long-continued light exposure of rhodopsin in solution will eventually bleach all the rhodopsin. The situation is different if thermal dissociation is arrested by low temperature[1,2]. In this condition, however great the light exposure, only about half the rhodopsin is found to have been bleached when measured after the subsequent thermal dissociation in the dark, and the half that remains has not quite the same absorption spectrum as the original rhodopsin.

In the living eye the thermal reaction cannot be delayed by low temperature but the same result may be obtained by bleaching with a powerful flash lasting 1 msec or so during which very little thermal change can occur. Hagins[3] in this way showed in the eye of decerebrate albino rabbits that only about half the rhodopsin content of the exposed retina could be bleached by a single flash no matter how bright this was.

The elegant analysis of Hubbard and Kropf[4] in solution at low temperature explained these phenomena. Before the irreversible thermal dissociation has occurred, the all-*trans* isomer still attached to opsin (metarhodopsin) is capable of reisomerization by light to form 11-*cis* which is rhodopsin, or 9-*cis* (isorhodopsin). Excessive light can do no more than produce the photo-equilibrium mixture of rhodopsin, isorhodopsin and metarhodopsin. The proportions depend somewhat on the colour of the light, but roughly half is metarhodopsin, and one-quarter each of the thermo-stable ingredients. This accounts for the fact that only half is bleached by the subsequent dark reaction and also for the final product being somewhat different from 11-*cis* rhodopsin, for it is a mixture of 11-*cis* and 9-*cis*.

Dark adaptation. It has long been held that the insensitiveness of the eye after exposure to strong light is closely linked to the bleaching and subsequent regeneration of the visual pigments. With regard to rod vision and rhodopsin this has now been placed on a fairly satisfactory footing by two rather different types of experiment. Dowling and Wald[5] exposed albino rats to bright lights and after various subsequent periods in the dark the threshold for the electroretinogram was taken; alternatively, the animal was killed and the rhodopsin content of the retina measured. A linear relation was found between rhodopsin content and log threshold.

This same linear result was found by Rushton[6] in man between the visual threshold for rods and their rhodopsin content as measured by reflexion densitometry in the living eye. As is well known, the dark-adaptation curve of the normal human eye consists of two branches, the first due to the cones which recover faster, the second to the rods which eventually become more sensitive. A difficulty in relating rod threshold with rhodopsin regeneration in man is that the rod threshold is normally hidden by the lower cone threshold for the first 15 min or so after a full bleaching exposure, and after 15 min rhodopsin is about 90 per cent regenerated, so there is little further regeneration occurring to relate with the 100-fold change seen in the rod threshold.

The most striking evidence was in fact obtained from a 'rod monochromat' who had normal rods and rhodopsin but very few cones; in that case the rod threshold could be followed well over a million-fold range of rod sensitivity.

Dark adaptation and flash bleaching. Now in the first section it appeared that a maximum brief flash only bleaches about half the rhodopsin to the unstable meta-rhodopsin and leaves half the pigment photosensitive in the form of rhodopsin and isorhodopsin. If isorhodopsin acts like rhodopsin in vision we might therefore expect from section 2 that dark adaptation, following a full flash bleach, will give the same result as that following a prolonged bleaching light that removed only half the rhodopsin.

Westheimer and I[7], working on rod dark-adaptation curves following flash bleachings, were surprised to find that the curve following a maximal flash (7 msec duration) was the same as that following a sustained exposure of 30 sec duration, also maximal in the sense that half that intensity lasting 30 sec gave the same dark-adaptation curve. The curves would be expected not to coincide but to run one about 4 min earlier than the other, which was certainly not the case. We had no densitometer at Berkeley and I have taken up the matter again at Cambridge with Dr. P. E. Hallett (Oxford) and Dr. H. D. Baker (Florida) as subjects.

Experiment. The results of bleaching with a bright flash (4 msec) or a 30-sec exposure were measured in a single experiment by bleaching in quick succession two retinal regions 5° apart, both 15° from the fovea. Just before and 15 sec after the bleach the change in rhodopsin density was measured at each retinal region. In confirmation of Hagins it was found that the 30-sec exposure produced about twice as much bleaching as did the flash. Dark-adaptation curves were then taken with a 2° test flash exposed for 0·25 sec each sec. The 2° test circle was half yellow and half blue of such relative intensities that they matched by rod vision and appeared a uniform grey circle. But by cone vision near threshold it appeared a yellow semicircle. It was thus easy to tell when the rod branch of the dark adaptation curve was reached.

Fig. 1 shows the rod branch of a dark-adaptation curve typical of many that have been obtained both from Dr. Hallett and from Dr. Baker. The black circles correspond to the results of flash bleaching, the white circles to a bleaching exposure of 30 sec. Since the latter light was extinguished 30 sec after the flash, the white circles in Fig. 1 have been displaced half a minute to the left so that both sets of points represent correctly the time that has elapsed from the end of the bleaching exposure. The coincidence is perfect and speaks for the skill of my two observers.

Discussion. Judged by reflexion densitometry a maximum flash only bleaches about half as much rhodopsin as is bleached by 30 sec of a maximum exposure; nevertheless the resulting rod dark-adaptation curves are exactly the same in the two cases. This is unexpected and some of our views about the course of pigment regeneration or its relation to dark adaptation will need enlargement.

One relation seems a simple starting point. Both the flash and the 30-sec exposure were maximal in the sense

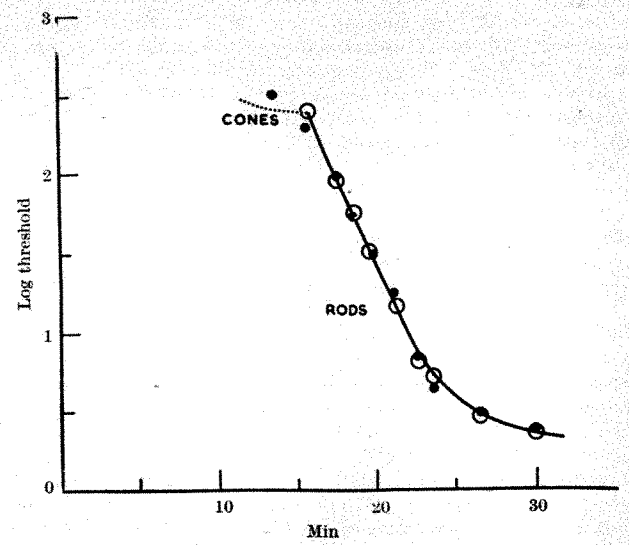

Fig. 1. Dark adaptation curve of rods (○) following a 30-sec exposure which appears to bleach away all the rhodopsin; (●) a 4 msec flash which appears to bleach only half. Cones are more sensitive than rods for the first 16 min. (Subject P. E. H.)

that doubling the intensity produced no further rise in rod threshold. Now this upper limit of threshold was in fact the same in the two cases so perhaps each light was able to push to the limit whatever change it is that causes the rod threshold to rise after bleaching. Unfortunately, however, it is not easy to reconcile this idea neatly with the known relation between threshold and the regeneration of rhodopsin.

A difficulty with rod adaptation in man is that following a maximal bleaching light we have to wait 15 min before rods are sensitive enough for their thresholds to fall below the cones and become measurable. If following the bleaching flash, rhodopsin regenerated more slowly than following the 30-sec exposure, perhaps 15 min later both retinal regions would be at about the same state of regeneration and thereafter march together.

This did not seem to me likely, but I had no knowledge of the isomers of retinene and their effect on regeneration, so I asked the experts, Hubbard and Dowling, when I visited Harvard recently. Their answer has been a series of excellent experiments on the rat which are described in the following communication. If in man the regeneration of rhodopsin follows the pattern they have shown so clearly in the rat it would account for our results. But with human rods I think that this is not the case, and with human cones I know that this is not the case.

Effects of Brilliant Flashes on Light and Dark Adaptation

Several years ago, Hagins[1] reported that a flash of light, no matter how intense, could not bleach more than about half the rhodopsin in a dark-adapted rabbit's eye, provided that it lasted no longer than 1 msec. This observation, though difficult to explain at the time, is a

direct consequence of the way in which light acts on rhodopsin[2,3].

Rhodopsin contains 11-*cis* retinal (formerly retinene)[4] attached as chromophore to a colourless protein, opsin. Light isomerizes the chromophore, predominantly to the all-*trans* configuration, and thereby produces a series of unstable intermediates: pre-lumirhodopsin, lumirhodopsin, metarhodopsin I and metarhodopsin II. These differ widely in their absorption properties, but all contain all-*trans* retinal still attached at the chromophoric site on opsin[5–7]. Finally, metarhodopsin II hydrolyses to all-*trans* retinal and opsin, and *in vivo* this is followed by the reduction of retinal to retinol (formerly vitamin A)[4].

The crucial point for Hagins's observation is that light isomerizes the chromophores of any of the all-*trans* chromoproteins—that is, the intermediates in which all-*trans* retinal is still at the chromophoric site—back in part to the 11-*cis* configuration, thus regenerating rhodopsin, and in part also to the 9-*cis* configuration, forming the rhodopsin analogue, isorhodopsin. In other words, any light which is bright enough to deliver large numbers of quanta within the relatively brief life-times of the unstable intermediates, isomerizes a fraction of them to rhodospin and isorhodopsin, and this fraction remains as a thermally stable but photosensitive residue, when the all-*trans* fraction has been hydrolysed to retinal and opsin (cf. refs. 8 and 9). No more photopigment (rhodopsin + isorhodopsin) can be bleached by increasing the intensity of a flash. What is now needed is time for the thermolabile all-*trans* chromoprotein to hydrolyse. As hydrolysis proceeds, fewer and fewer chromophores are available to absorb the light and be isomerized by it, until eventually all the rhodopsin and isorhodopsin have been converted to retinal and opsin. How much time this requires depends on the light intensity and the temperature. The former determines the rates of the photo-isomerizations (initially from 11-*cis* to all-*trans*, but shortly also from all-*trans* to 11-*cis* and 9-*cis*); the latter, the rate of hydrolysis.

In the preceding communication Rushton has outlined the paradox which arises from these reactions. He finds that following an intense, short flash, the course of human rod dark adaptation is essentially the same as after a longer exposure to bright light, which bleaches about twice as much photopigment. This is surprising, for ordinarily bleaching more photopigment produces a higher state of light adaptation, and therefore prolongs dark adaptation. Many years ago, Wald and Clark observed that following a photoflash of 20–40 msec duration, human dark adaptation was very slow, as though from a high state of light adaptation[10]. (A photoflash leaves a residue of about 35 per cent photoregenerated rhodopsin + isorhodopsin.) The inconsistency between these results and Hagins's discovery of the low efficacy of flashes of light to bleach rhodopsin, however, went unnoticed until Rushton juxtaposed the two types of observation in one experiment.

After Rushton told us about his observations (personal communication), we decided to examine this phenomenon in the albino rat, which has the advantage over most other vertebrates that its electroretinogram (ERG) behaves as though it had an all-rod retina, though its retina is known from anatomical studies to contain a few cones. In the albino rat one can therefore observe the entire course of rod dark adaptation as well as of rhodopsin formation[11,12]. We have light adapted our animals with a xenon flash gun ('Ultrablitz Meteor *SP*') held at a distance of about 4 in. from the eye. The flash has an intensity rating of about 80 W sec delivered in 1 msec; but we measure a peak in intensity at about 0·7 msec. after which it decays with a half-time of about 2·5 msec. Visual thresholds are determined by means of the ERG; photopigment concentrations by direct extraction[11,12].

A single flash delivered by our flash gun leaves the eye of the albino rat with about 35 per cent photopigment, with λ_{max} 496 mμ. The λ_{max} of rat rhodopsin is at 498 mμ, and that of isorhodopsin is shifted about 12 mμ to shorter wave-lengths. The photoregenerated pigment therefore contains roughly a 5 : 1 mixture of rhodopsin and isorhodopsin.

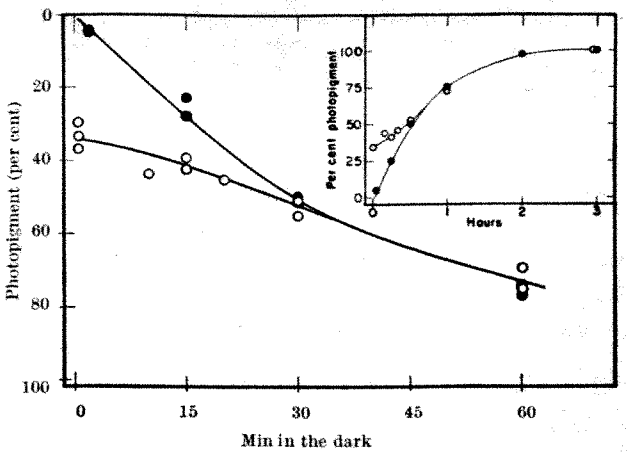

Fig. 1. The course of rhodopsin formation in the albino rat following light adaptation by a xenon flash gun (open circles) or by 30 min exposure to bright white light (filled circles). Prior to light adaptation with the flash gun, each animal was lightly anæsthetized with ether. The two eyes were light adapted successively, and each experimental point represents the results obtained with the two eyes of one animal. Unless the eyes were to be enucleated immediately on light adaptation, the animals were allowed to recover in the dark, and were anæsthetized with ether and nembutal just before removing the eyes. For the prolonged light adaptation, untreated animals were kept in a white enamel pan, and observed periodically to prevent them from shielding their eyes; they were then anæsthetized deeply just prior to enucleation of the eyes. Rhodopsin was prepared as described in ref. 12, and its concentration expressed as the percentage of photopigment found in the completely dark-adapted eyes (see inset). Experimental points in the inset are averages; in the main part of the figure, they are results obtained with individual animals. As can be seen, these are reasonably reproducible among different animals

Fig. 1 illustrates the way in which rhodopsin accumulates in the dark in animals light adapted by a single flash (1 msec) (open circles). The concentration of photopigment increases slowly during the first 20–30 min, so that after about 30 min in the dark, the flash-adapted eye (open circles) contains no more photopigment than an eye in which essentially all the rhodopsin had been bleached by prolonged adaptation to bright light (30 min) (filled circles). Thereafter, rhodopsin accumulates at about the same rate following both types of adaptation. (Both rhodopsin and isorhodopsin are formed in the light; but only rhodopsin is regenerated in the dark.) In other words, following a flash, the course of rhodopsin synthesis is S-shaped, and joins the dark-adaptation curve from a much higher state of prolonged light adaptation after about 30 min in the dark (see inset to Fig. 1). It therefore takes a flash-adapted eye as long to recover completely as one in which much more rhodopsin had been bleached away by prolonged light adaptation.

The ERG threshold recovers in a similar way. As shown in Fig. 2, a single flash of light (1 msec) raises the threshold about 3·75 log units above the dark-adapted level (open circles). (The threshold is measured 1 min after the flash, after the bulk of the initial rapid changes of threshold —presumably due to the neural component of dark adaptation—are completed[12]). This rise of threshold corresponds roughly to a rhodopsin concentration of about 35 per cent. Then, during the first 20–30 min in the dark, the threshold falls very slowly, so that after about 30 min in the dark the dark-adaptation curve of the flash-adapted eye joins that of an eye which has been light adapted to a much higher threshold by prolonged exposure to bright light (5 or 10 min) (filled circles).

Also shown in Fig. 2 is the dark-adaptation curve measured after prolonged adaptation to a dimmer light, which raises the threshold only about 3 log units above the dark-adapted level (half-filled circles). In this case, the threshold recovers in much the same way as after prolonged

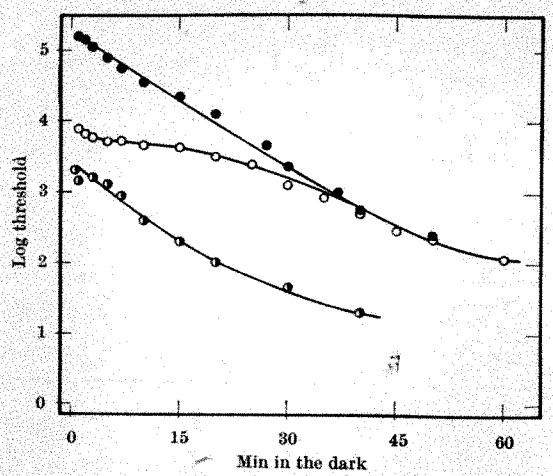

Fig. 2. Recovery of visual sensitivity following light adaptation with a xenon flash gun (open circles) or to bright white light for 5–10 min (filled circles). The course of dark adaptation after 5 min adaptation to white light of 1/10 the intensity is shown by half-filled circles. The animals were light adapted as described in Fig. 1, except that all animals were anæsthetized with nembutal (5 mg/100 g body-weight) during the entire course of light and dark adaptation, and allowed to recover at the end of the experiment. The ERG thresholds were determined as described in ref. 12

adaptation to the ten times brighter light, along an entirely different course from that observed after a flash.

In summary, a short, brilliant flash, which photo-regenerates about 35 per cent photopigment, raises the threshold to a level which corresponds roughly to the presence of that amount of visual pigment. Following the flash, rhodopsin accumulates very slowly during the first 20–30 min in the dark, and there is a correspondingly slow fall of threshold. After about 30 min in the dark, both functions join the recovery curves from a much higher state of prolonged light adaptation.

These observations agree with Rushton's, and serve to resolve them. In man, the initial stages of rod dark adaptation are obscured by the lower thresholds of the cones, so that one sees only the final coincidence of rod dark adaptation following a flash and following prolonged adaptation to bright light.

One reason why the flash causes an initial delay in rhodopsin formation is clear from what has already been said. For the very fact that the flash causes photo-regeneration implies that the quanta are delivered within the life-times of the all-*trans* chromoproteins, that is, before retinal has left the chromophoric site. Immediately after the flash, that fraction of opsin molecules which does not already possess an 11-*cis* or 9-*cis* chromophore, therefore cannot combine with 11-*cis* retinal until the all-*trans* isomer hydrolyses off the chromophoric site. It is easy to demonstrate a competition between the hydrolysis of metarhodopsin and the formation of rhodopsin in solution, that is, the competition between all-*trans* retinal on the site and 11-*cis* retinal seeking to occupy it. The presence of an excess of 11-*cis* retinal accelerates the disappearance of metarhodopsin I; and conversely, rhodopsin is regenerated more slowly if 11-*cis* retinal is added immediately after it has been bleached, than if it is added 2 h later, when all the all-*trans* chromoprotein has been hydrolysed in the dark.

It has sometimes been suggested that the retina may possess enzymes which isomerize one or another of the labile intermediates back to rhodopsin, while the all-*trans* chromophore is still attached to the chromophoric site[13]. This type of isomerization reaction almost surely takes place in lobsters, squid and other cephalopods, in which retinal apparently never leaves the chromophoric site *in vivo*[14–16]. The experiments described here show that this reaction does not occur in rats or men during dark adaptation. Nor does it seem to occur in frogs, where Zewi many years ago observed a delay in rhodopsin formation, precisely under conditions comparable with those delay it in the present experiments: namely, follov brief exposures to bright light, particularly at low temp ture[17]. It is therefore likely that all vertebrates regene rhodopsin in the dark only from free retinal and ops

This introduces a second reason for the initial dela rhodopsin synthesis. For if rhodopsin must be for from 11-*cis* retinal and opsin, the availability of 11 retinal is crucial to the rate of regeneration. The all rat, when dark adapted, contains little free ret or retinol[18]. The hydrolysis of the all-*trans* intermedi therefore not only clears the chromophoric site on op but is the main source of retinal or retinol for isomer tion to the 11-*cis* configuration and rhodopsin synth This factor does not have the same force in frogs a albino rats, since frogs store considerable retinol in t eyes, and some in the 11-*cis* configuration[19].

The length of the initial delay is necessarily also affec by the rate at which opsin combines with 11-*cis* reti This depends on the affinity of opsin for retinal, as as on their respective availabilities. The affinity is kn to differ in rod and cone opsins from the same anim and also among rod opsins from different animals[21]. I therefore impossible beforehand to predict the extent the delay in a specific animal or experimental situati

In general, one would expect it to be more pronoun in the albino rat than in most other warm-bloo vertebrates, since rhodopsin formation in the rat is v slow; much slower, for example, than in man[11,18,22]. the albino rat, we observe an initial slowing of d adaptation even after adaptations to bright lights last up to 1 min, though the lag under these circumstan lasts only 5 or 10 min (cf. Fig. 4, ref. 13). No delay usually seen after light adaptations of more than 5 m even if these are produced by repeated flashes, rather t by a steady bright light. As seen in Fig. 3, it takes li plus time in the dark to abolish the delay, just as both required to bleach all the photopigment. The two effe go hand in hand, since both are caused by the persiste of all-*trans* retinal on the chromophoric site.

The open circles in Fig. 3 summarize experiments which the albino rat has been exposed to successive flas delivered 2–5 min apart, thresholds being measured min after each flash. The first flash raises the thresh

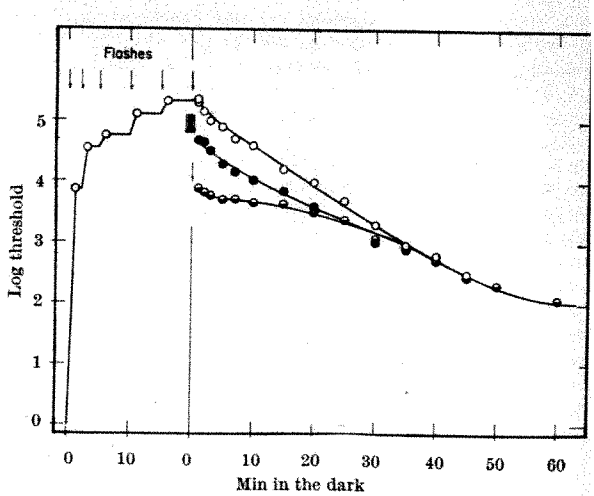

Fig. 3. Effectiveness of short, brilliant flashes to light adapt the eye, and the subsequent course of dark adaptation. The eyes of anæsthetized albino rats were exposed to flashes from a xenon flash gun, and the ERG threshold measured as described in ref. 12. Open circles are averages from three experiments, in which the eye was exposed to six flashes of light delivered in the course of 20 min at the times shown by the arrows, the threshold always being determined 1 min after the flash. Filled circles are averages from five experiments, in which the eye was exposed to the same number of flashes, all delivered within 1 min. The half-filled circles, averages from six experiments, show the results of exposing the eye to a single flash (cf. Fig. 2). The course of dark adaptation in each case is shown only for the first hour, by which time all three curves coincide. But dark adaptation is not complete until the animals have been in the dark about 3 h (cf. Fig. 1)

by about 3·8 log units (cf. Fig. 2), the second about 0·7 log unit further. Succeeding flashes raise it less and less, until it is raised about 5·3 log units, corresponding to a rhodopsin content of 1–2 per cent[12], and cannot be raised further. This takes about 6 flashes delivered over a period of 10–15 min.

If 6 flashes are delivered within 1 min (Fig. 3, filled circles), the threshold is raised only about 4·7 log units, about the same level as after only 2 flashes spaced 1–2 min apart. In other words, 6 flashes bleach no more rhodopsin than 2 flashes, unless they are spaced sufficiently widely apart to let some of the all-*trans* chromophore be hydrolysed from opsin. In both cases, recovery follows an intermediate course between that observed after a single flash (Fig. 3, half-filled circles), and that seen after complete bleaching by 6 or 7 flashes spread over 15 min; and all three curves coincide roughly after about 35 min in the dark.

We have measured the rise in visual threshold also during adaptation to continuous bright light. In the albino rat, the brightest lights we have tested cannot raise the threshold more than about 4·5 log units during the first min, the same as 2 or 6 flashes spaced over 1 min. This probably represents the limit imposed by the rates of the relevant thermal reactions at body temperature. As might be expected, all these lights produce a similar initial lag in dark adaptation. The time required to dark adapt completely is again the same as in rats the rhodopsin of which has been bleached completely by prolonged light adaptation.

CRYSTALLIZATION OF ω-DICARBOXYLIC ACIDS IN POLYMER FILMS

By DR. H. A. LANCELEY, DR. G. N. RICHARDS, and DR. L. ROLDAN-GOZALEZ*
AMF British Research Laboratories, Blounts Court, Sonning Common, Reading

IT is well known[1] that the environmental conditions under which crystal growth occurs can have a marked influence on the external visible shape of certain crystals. This effect is manifested in two ways. In single crystals the crystal habit may vary either because the growth develops on different crystal planes or because the relative development of the same set of faces differs. Alternatively, when the entities actually observed are not single crystals, but are aggregates (for example, spherulites) consisting of crystalline sub-units such as crystallites or fibrils, the visible shape of the aggregates will be determined by the size and orientation of these sub-units. This applies especially to polymeric materials.

A number of unusual crystalline modifications, resulting from particular conditions of growth, have been reported from time to time. Thus, there are many references to changes of habit in single crystals of simple inorganic salts[2–7]. Rarer forms such as curled platelets in paraffin wax have been observed by Edwards[8], and helical structures have been seen in micro-crystals of certain soaps[9] and in sublimed zinc sulphide[10].

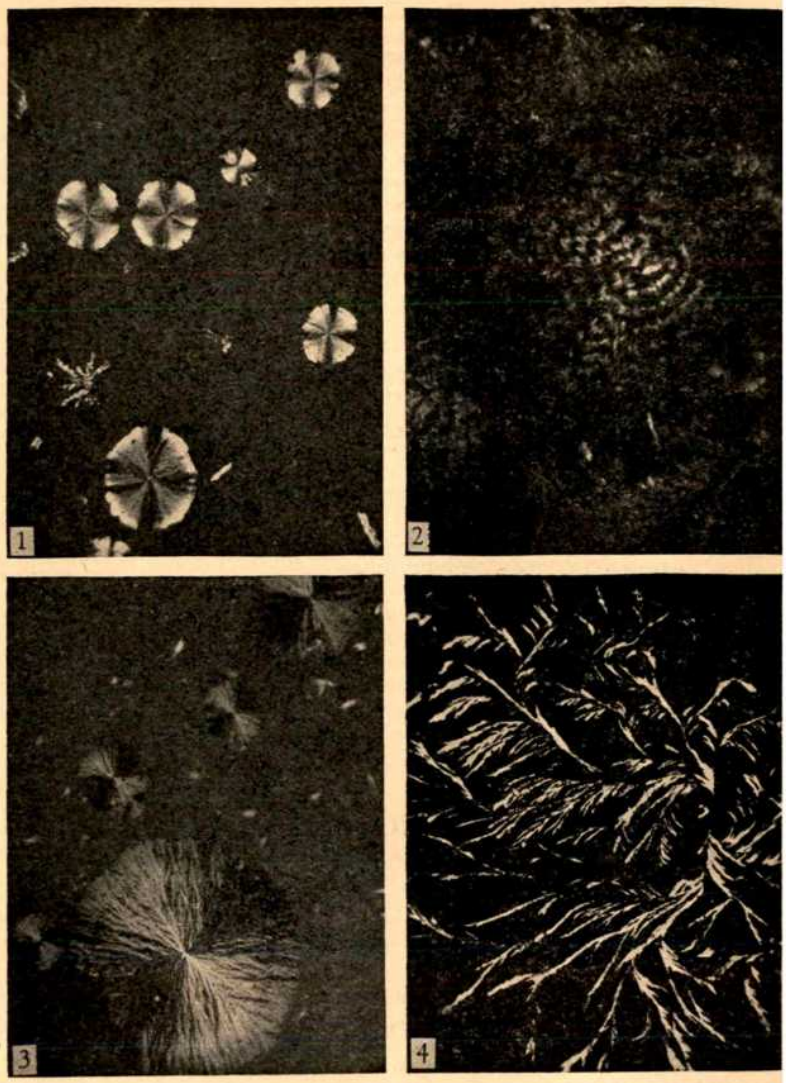
Irregularly branched dendritic crystalline aggregates occur in many systems[2]; usually under conditions where a high degree of super-cooling or super-saturation can be achieved. Spherulitic crystalline aggregates, first observed in certain minerals, are now frequently found in melt crystallized polymers[11] (though polymer single crystals[12] can also be grown from very dilute solutions). However, many simpler organic substances, for example, sucrose[13], resorcinol[14], malonamide[15,16], and hydroquinone[15], and the many inorganic salts studied by Morse and Donnay[17], all of which are normally grown from solution in the form of single crystals, can also be made to crystallize in spherulitic form if the experimental conditions are suitably chosen.

The purpose of the present communication is to report microscope observations of a wide range of birefringent crystalline forms, and notably spherulitic forms, which appear in solution-cast polymer films containing ω-dicarboxylic acids. The work stems from the adventitious inclusion of oxalic acid in an aqueous dispersion of pectic acid which when dried out exhibited spherulitic and dendritic structural features. Similar forms were subsequently observed in films of poly (vinyl alcohol) and poly (vinyl chloride) containing ω-dicarboxylic acids and these observations therefore provide a further example of the effect of environment on crystal growth.

The pectic acid was extracted from Bright or Connecticut Broad Leaf tobacco stems by the methods of Masters and Richards[18]. Poly (vinyl alcohol) was supplied by L. Light and Co., and poly (vinyl chloride) as compound '*RA*124' from British Geon, Ltd. Adipic and sebacic acids used were laboratory grade reagents recrystallized from aqueous solution and oxalic acid was Analar grade.

In the earlier experiments pectic acid, partially neutralized with sodium hydroxide and containing about 5–10 per cent oxalic acid and 30–50 per cent glycerol, was used. The films were cast from aqueous solution at 20° ± 1° C and 65 ± 2 per cent relative humidity. Birefringent structures began to form in the films during the later stages of removal of water and the structures often continued to grow for several days. In subsequent experiments both casting temperature and concentration of oxalic acid were systematically varied and the glycerol was omitted. The films gave a crystalline X-ray diffraction pattern,

* Contributed to this work at the British Rayon Research Association, Wythenshawe, Manchester. Present address: Allied Chemical Co., Morristown, New Jersey.



dependent on the extent of neutralization (cf. ref. 18). Crystalline diffraction was also observed in the absence of oxalic acid, although such films were completely non-birefringent.

Several different types of birefringent entities, namely, spherulites, spheruloids and dendritic formations were distinguished in the different films and certain trends are apparent in the type of structure formed. For example, as the casting temperature was increased entities became less complex and more numerous and at 75° C extensive nucleation occurred producing a very grainy birefringent appearance throughout the film. A similar effect was noted with increasing neutralization of the pectic acid. No systematic influence of glycerol content on the structures could be detected. Particular forms could not be identified with films of particular oxalic acid content when the latter was varied from 5–20 per cent, and it is evident that local concentration fluctuations and conditions are more important than the overall ratio of pectic to oxalic acid. Although birefringent structures formed during the later stages of the evaporation of solvent, controlled evaporation in enclosures of constant but different relative humidity did not appear to lead to the production of specific forms. Very rapid removal of water in high vacuum, however, generally caused less dense, highly branched dendritic growths. On standing for 2–3 days at 20° C, 65 per cent relative humidity, dendritic structures in thin films cast from 0·5 per cent solution coalesced to form well-defined single crystals of oxalic acid.

The phenomenon is not specific to the pectic acid/oxalic acid/water system. Thus in films cast under ambient conditions from 10–20 per cent (w/w) poly (vinyl alcohol)/water solutions containing oxalic acid a similar wide range of dendritic and spherulitic structures was produced. Adipic acid and sebacic acid were also shown to be effective and spherulites of the latter could be grown within the 20 per cent poly (vinyl alcohol) solution. These entities when subjected to small shearing stress yielded radically cleaved fragments. Sodium oxalate usually produced only single crystals in poly (vinyl alcohol) films, but these sometimes appeared in the form of dendritic or spherical agglomerates.

Solution cast films of pure poly (vinyl alcohol) are partially crystalline but are not birefringent. However, poly (vinyl chloride) is neither crystalline nor birefringent and this polymer was also found to provide a medium in which ω-dicarboxylic acids would crystallize in birefringent and spherulitic forms, in this case from *cyclo*hexanone solution. A similar observation has been made recently by Schuur[19].

Examples of typical structures in the systems studied are shown in Figs. 1–4.

		Casting solution	Film thickness (mm)	Scale (field diameter, mm)
Fig. 1.	Spherulites	16 per cent w/w poly (vinyl alcohol)/water. Oxalic acid 30 per cent	0·05	1·0
Fig. 2.	Ringed spherulites	0·4 per cent w/w pectic acid/water; *p*H = 3·6. Glycerol 40 per cent, oxalic acid about 10 per cent	0·05	1·0
Fig. 3.	Spheruloids	20 per cent w/w poly (vinyl alcohol)/water. Oxalic acid 20 per cent	0·05	1·8
Fig. 4.	Dendritic structure	0·3 per cent w/w pectic acid/water; *p*H = 3·6. Glycerol 50 per cent, oxalic acid about 10 per cent	0·01	2·4

Solution *p*H adjusted using 5 N sodium hydroxide solution. Plasticizer and dicarboxylic acid content expressed as percentage dry weight of polymer. All samples were viewed between crossed polaroids, the axes of which were parallel to the edges of the photographs

Numerous, but unsuccessful, attempts have been made to induce the low-molecular-weight dicarboxylic acids to crystallize in other than the normal crystal form without added polymer. Dendritic oxalic acid crystals have been grown when thin layers of a dilute solution were allowed to evaporate, but the dendrites appear to be agglomerates of single crystals. Single crystals were also obtained from organic solvents such as acetone, ethanol, or glycerol, without any obvious change in the habit of the acid crystals. One notable exception however was the production of long needles (10–20 mm × about 1 mm diameter) of adipic acid from a saturated solution in xylene.

Since a similar wide range of crystalline forms is observed in films of polymers which are different chemically and which are either crystalline or non-crystalline, with the ω-dicarboxylic acids the only common factor, it seems reasonably certain that these are structures of the ω-dicarboxylic acids themselves.

From saturated aqueous solution, however, the lower dicarboxylic acids appear in the form of single

crystals, usually short monoclinic needles, so that the polymers present in the system studied here evidently exert a controlling influence over the crystallization process.

It is generally accepted that crystallization proceeds via consecutive nucleation and growth steps and in so far as single crystal growth is concerned the mechanism is quite well understood. Now it would not be unreasonable to suppose that the observed structures stem from single crystal nuclei. We must, therefore, conclude that the number of effective nuclei is limited and that the subsequent development is also modified by the polymer.

There are many instances of the supression of homogeneous nucleation in media of high viscosity. Glasses are often formed for just this reason. Again, certain polymeric materials, which normally exist in a crystalline form, may exist indefinitely in a non-crystalline state if quenched from the melt to temperatures where the high viscosity hinders the formation of crystal nuclei. Concentrated aqueous solutions of sucrose[13] may be maintained for long periods at high degrees of super-saturation without crystallization taking place, and it has been stated[16] that nucleation is also greatly diminished in melts of low molecular weight materials, for example, malonamide and resorcinol, to which certain colloids have been added to increase the viscosity.

It is now suggested therefore that, in the solutions and films under consideration here, the viscosity is so increased by the presence of the polymer as to reduce greatly the rate of formation of effective crystal nuclei of the dicarboxylic acids.

If limitation of nuclei were the only effect of the polymers on crystallization of the dicarboxylic acids, however, the result would be to prevent their crystallization or to produce a few large 'normal' crystals. We must therefore seek factors which favour spherulitic and dendritic forms of growth.

The ability to form long needle-shaped crystals or fibrils is an important property in this respect and very probably a necessary requirement for the production of dendritic and spherulitic structures. The lower ω-dicarboxylic acids adopt an acicular habit when grown from aqueous solution and this inherent tendency is almost certainly encouraged under the present conditions. For example, the preferential growth of 'thin stemmed' crystals has long been known to be favoured in a medium of high viscosity[20]. Furthermore, similar though apparently specific effects on crystal habit have been noticed in the presence of relatively small concentrations of added colloidal substances or polymers. Among the latter, and of particular significance, is the effect of pectic acid[6] or poly (vinyl alcohol)[7] in promoting the formation of fibrous or needle-shaped crystals from aqueous solutions of inorganic salts.

The ultimate formation of dendritic or spherulitic structures from a needle-shaped nucleus or a bundle of needles must, however, depend on a twinning or branching process. This would lead to intermediate sheaf-like forms composed either of fibrillar single crystals or fibrillar aggregates of crystallites. Spherulite precursors of just this shape have indeed been observed in the present work. Subsequent growth would then develop to give the large-scale aggregates with more or less spherical symmetry exhibiting a radially oriented fibrous fine structure. With one exception[19] this type of mechanism forms the basis for the hypotheses proposed to account for spherulite growth and in general terms at least has proved adequate. Keith and Padden[21] have recently presented a unified theory of spherulite growth which is dependent on the presence of more than one component on high viscosity and on slow crystal growth. All these factors are present in our systems, and, furthermore, dendritic and spherulitic crystalline aggregates appear in the same film. It is likely, therefore, that the growth mechanisms of the two forms should not be too different and that both could arise from branching or twinning of needle-shaped crystals as outlined above.

Dendrite formation occurs more frequently where crystallization is able to occur rapidly, as in the very thin films or when solvent is removed rapidly under high vacuum. Open, irregularly, branched structures are apparently then a consequence of a high degree of supersaturation and rapid growth. This is consistent with the generalization of Buckley[2] on factors favouring dendritic growth.

The spherulites, on the other hand, have grown slowly. They are more condensed structures and evidently consist of a more symmetrical arrangement of crystalline sub-units, as is revealed by the extinction cross (Fig. 1) or rings (Fig. 2) produced when these entities are viewed between crossed polaroids. Their resemblance to spherulites often seen in melt crystallized polymers is striking and suggests the following explanation for the wide variety of crystalline forms observed here.

The acicular crystals of the lower ω-dicarboxylic acids consist of arrays of linear chains of molecules linked together head to tail through hydrogen bonding between carboxyl groups[22]. In addition, it is frequently found that the molecular chain axis lies perpendicular to the long axis of the crystals, a fact which is consistent with a growth mechanism involving lateral accretion of chains or chain segments. It is possible, therefore, that molecular associations of this type to form linear chains precedes crystallization in the systems investigated here. This would then lead to the analogy with melt crystallized polymers, the various crystalline forms possibly arising from a range of chain lengths which determine the mobility of the crystallizing species. Observations of dendritic (herring-bone) spherulites in low molecular weight polypropylene[19] and in a low molecular weight fraction of polyethylene[23], support the proposal that chain length may be an important factor in determining spherulite fine structure.

It is not suggested that linear chains of molecules are always necessary before crystallization can occur in spherulitic form. Indeed, the work of Morse and Donnay[17] describing ringed spherulites in a wide range of inorganic substances of different chemical types shows that such a generalization is unwarranted. The results described above, however, indicate that the unusual crystalline habits of these dicarboxylic acids are probably due to both linear intermolecular association and increased viscosity due to the base polymer, these two effects being interrelated.

POSSIBLE TRANSITION IN THE INITIATING MECHANISM LEADING TO ELECTRICAL BREAKDOWN IN VACUUM

By Dr. R. HAWLEY
Corona Group, C. A. Parsons and Co., Ltd., Newcastle upon Tyne

MANY experiments have been carried out to determine the initiating event leading to electrical breakdown between metallic electrodes separated by high vacuum[1,2]. While the mechanism causing breakdown in certain cases, such as when using sharply pointed cathodes in extremely clean conditions, is now understood, the more practical case of plane-parallel electrodes with mechanically polished and oxidized surfaces is still under active investigation[3].

Of the mechanisms thought to cause breakdown, those that have received most attention are:

(*a*) those in which discrete beams of electrons, from small areas or asperities on the cathode, bombard areas on the anode. Resistive heating effects at the cathode or bombardment effects at the anode cause localized rises in temperature and the release of gases or vapours in which low pressure gas breakdown can occur;

(*b*) those in which the transport across the gap of aggregates of material, or clumps, and their resultant impact on the opposite electrode gives rise to heating and hence to the release of vapour.

The Electron Beam Mechanism. The mechanism of electron beams causing anode heating was first suggested by Semenov[4] and has been supported by the comprehensive experimental and theoretical work of Maitland[5,6] and by others. Maitland showed that craters were produced on the anode during the breakdown process and he postulated that these were due to the existence of a multiple system of electron beams in the gap initiating breakdown. That copious electron emission occurs from metallic electrodes, having mechanically polished and oxidized surfaces, at the stresses noted by the foregoing investigators (in the region of 5×10^5 V/cm) has recently been confirmed[7].

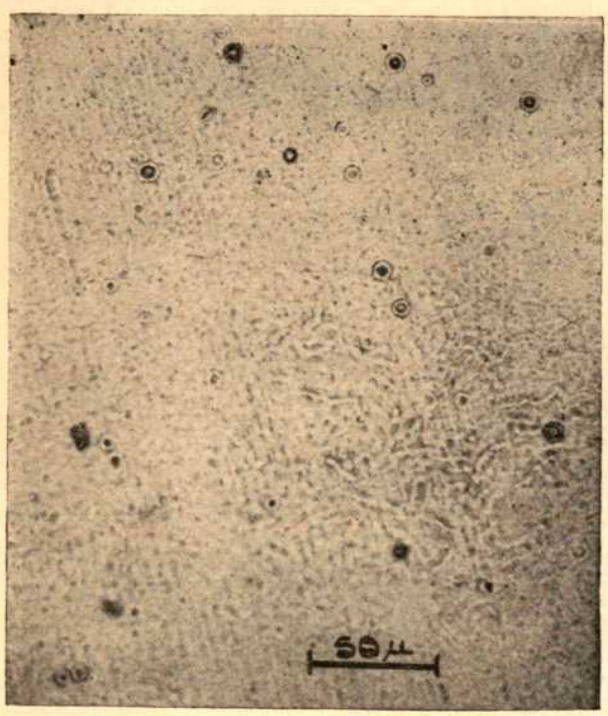

Fig. 1. Pre-breakdown markings on anode of commercial copper. Gap = 1 mm

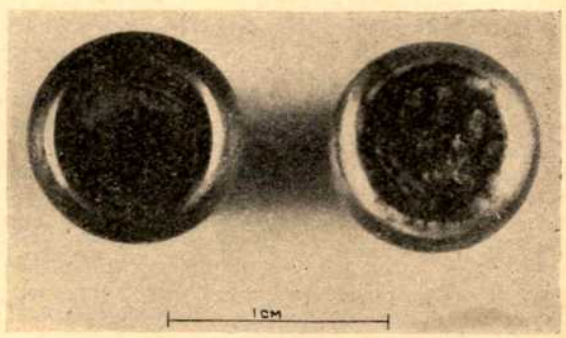

Fig. 2. Markings after ten breakdowns between copper electrodes in a 1-mm gap. Breakdown voltages = 30–40 kV

Hawley and Walley[8] attempted to see if evidence of the presence of clumps could be obtained, in gaps up to 0·75 mm, by observing pre-breakdown surface effects at copper anodes through a microscope. Though embedded inclusions were torn from the anode they did not initiate breakdown on crossing the gap. In addition, 'spots' sometimes appeared on the anode prior to breakdown, at stresses of about $4–6 \times 10^5$ V/cm. More recent analysis of these spots, using an interference microscope, has shown they are craters (Fig. 1) similar to those reported by Maitland[6], consisting of a pip in a central depression surrounded by a raised rim; and so it can be assumed they are caused by electron beam heating.

The maximum gap studied by those investigators postulating an electron beam mechanism is 2 mm. The bigger the gap the larger the area bombarded at the anode by the divergent electron beam, so the greater the input power at the surface required for breakdown. However, Trump and Van de Graaff[9], using gaps of 0·25 mm to 70 mm, showed that as the gap is increased the cathode gradient (where gradient is taken as voltage divided by gap and no account taken of intensification factors due to the surface condition) required for breakdown decreases rapidly so that the electron emission must also decrease (also see ref. 10). This is the opposite to what would be expected if the electron beam mechanism were applicable to all gaps.

The Clump Mechanism. In small gaps a clump may possess insufficient energy to cause breakdown due to it being accelerated by a low voltage. In longer gaps, because of the higher voltage required to produce breakdown, the clump energy would be correspondingly increased and a clump mechanism may be possible. Thus as the gap is increased this mechanism may take preference over an electron beam mechanism.

One objection to a clump mechanism is that as the electrical stress required for breakdown falls with increasing gap, so also must the electrostatic forces available to remove a clump from the surface of the electrodes. However, studies of electrode surfaces after breakdown in 20 mm gaps[11] have shown that clumps can exist even at

stresses as low as 4×10^4 V/cm though it was not possible to show that clumps were responsible for the actual initiation of the breakdown. This has long been an experimental difficulty. Since the existence of clumps is proved, one approach would be to study the characteristics of the breakdown mechanism, in gaps of increasing size, to see if evidence of a transition in the initiating event can be found. This can be done by examining the markings on the electrodes after breakdown has taken place and also by noting the shape of the breakdown voltage-gap curve.

Evidence of a Transition. Studies of the breakdown markings in small gaps (up to 2 mm) have shown that the electron beam mechanism is characterized by craters on the anode surface[6,12]. With similar conditions and using uniform field electrodes, 1 cm and 2·5 cm in diameter and gaps up to 5 mm, the markings occurring after ten breakdowns were studied. Direct voltages were used, the voltage level being gradually increased until breakdown occurred. After ten such voltage applications the electrodes were removed, examined, repolished to a 1μ diamond paste finish and replaced in the cell ready for the next test. Fig. 2 illustrates the gross markings, on commercial copper electrodes, that were typical for gaps of 0–1 mm. Each gross mark on the anode contained craters (Fig. 3). In 2-mm gaps the number of craters and the severity of the gross markings were reduced while in 3-mm and larger gaps the character of the markings had changed completely. At the anode no gross markings or craters were found. This difference in the markings could therefore be taken as evidence of a change in the breakdown mechanism.

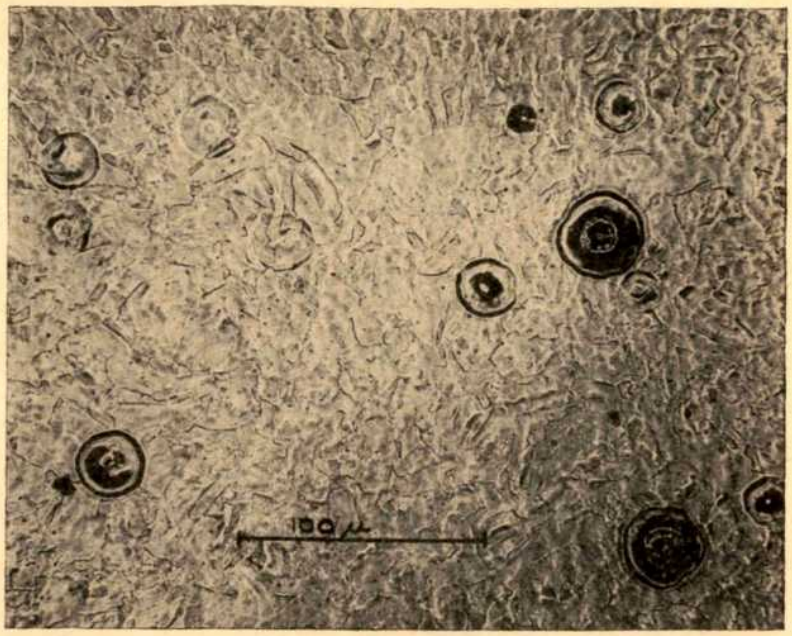

Fig. 3. Melting and cratering effects on anode of commercial copper. Gap = 1 mm. Breakdown voltages = 30–40 kV

An empirical relationship between the electrode spacing and the breakdown voltage is:

$$V = kd^{\alpha} \qquad (1)$$

where V = breakdown voltage
d = gap
k and α = constants, depending on experimental conditions

The Maitland hypothesis[6], based on electron beams, predicts $\alpha = 0{\cdot}8$, while the Cranberg[13] and Slivkov[14] hypotheses, based on clumps, predict $\alpha = 0{\cdot}5$ and 0·625 respectively. Therefore, another way to detect any change in the breakdown mechanism is to obtain the breakdown voltage-gap curve and see if a change occurs in the value of α with increase in gap.

Once a breakdown has taken place in a vacuum gap it is possible that the arc, by causing melting, etc., could give rise to the formation of clumps at the electrode surface. Also the value of α has been shown by Maitland to depend on the previous number of breakdowns in the gap[15]. Therefore to avoid variation of α due to experimental procedure and also to avoid the possible formation of clumps by the arc, values of the first breakdown voltages have been obtained between freshly polished uniform field electrodes[2]. For gaps below 5 mm, 2·5-cm diameter electrodes and direct voltages were used, for 5 mm and greater gaps, 7 cm diameter electrodes and negative 1/50 wave impulse voltage were used. In all cases the vacuum was of the order of 10^{-5} torr, and after each breakdown the electrodes were removed and repolished to a 1μ diamond paste finish.

The magnitudes of the first breakdown voltages obtained in this manner for stainless steel and for copper electrodes are given in Fig. 4, the slope of the curves being α. There is an apparent change in α at 17 mm for stainless steel electrodes and at 7 mm for copper electrodes (Table 1). Slivkov[14] measured the breakdown voltages

Table 1. VALUES OF α

Electrode material	Values of α	
	Small gaps	Large gaps
Stainless steel	0·58	0·19
Copper	0·53	0·29

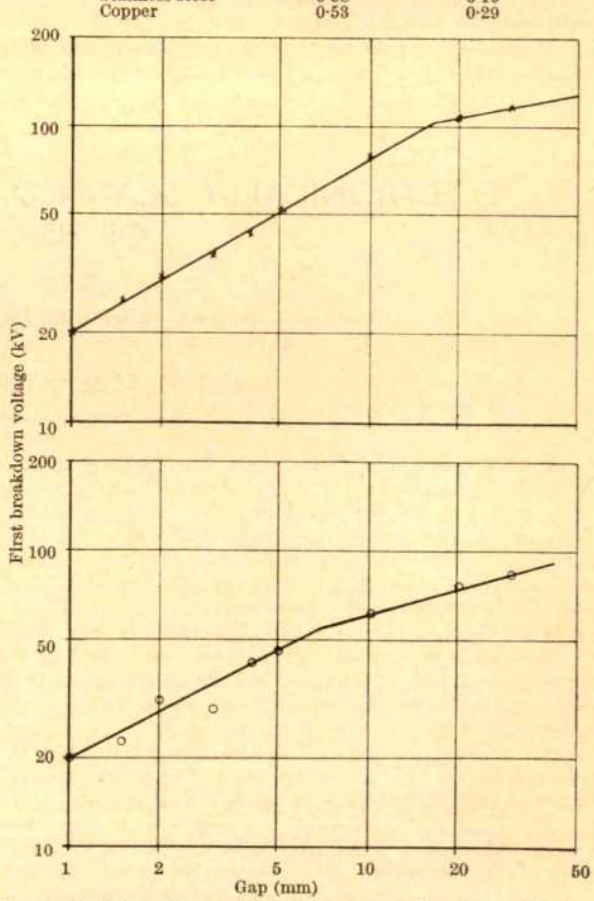

Fig. 4. First breakdown voltages between smooth uniform field electrodes in vacuum. Above, Steel electrodes; below, copper electrodes

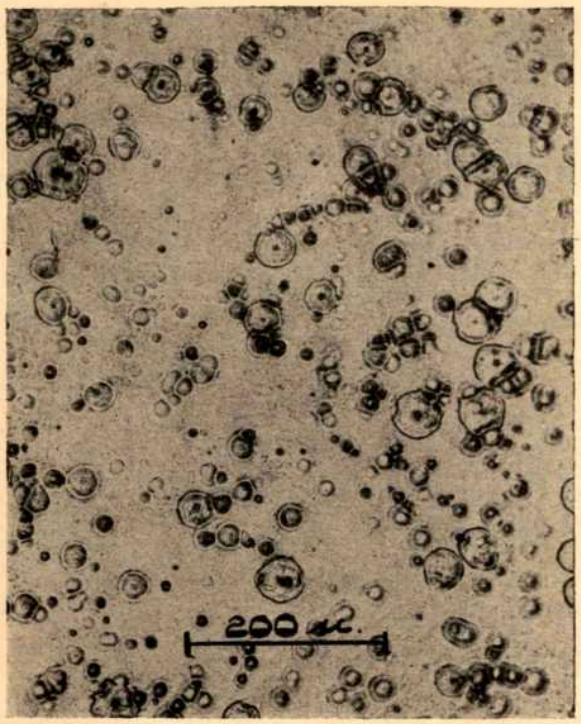

Fig. 5. Markings on anode of stainless steel after impulse voltage breakdown. Gap = 20 mm

between steel electrodes in gaps up to 8 mm and adjusted his theoretically obtained equations to suit the values found by experiment. Under the present experimental conditions the critical gap for stainless steel is about 17 mm so that it is possible that Slivkov was not observing a clump-type breakdown. If this was so then his value of 0·63 for α is in good agreement with the present value of 0·58 obtained for stainless steel for the smaller gaps.

The foregoing results are highly tentative and need to be confirmed using a consistent type of voltage before any definite conclusions are drawn. Also there is conflicting evidence as to the gap regions in which the different mechanisms apply. For example, in several tests using 20 mm gaps (that is, gaps greater than the apparent critical gap) and stainless steel electrodes, markings were found on the anode (Fig. 5) identical to those reported by Maitland[16] which he attributed to an electron beam mechanism. In addition, Rozanova[17] has recently shown, by deliberately introducing clumps on to clean electrodes, that clumps can initiate breakdown in gaps as small as 0·4–0·8 mm.

Obviously the critical gap will depend strongly on the experimental conditions, for example, the state of the electrode surfaces, the electrode material, etc., but the above results, although obtained using different types of voltages, provide some evidence of a change in the breakdown mechanism in vacuum with increase in gap.

I thank the Directors of C. A. Parsons and Co., Ltd., for permission to publish this article and Dr. R. L. Craik, Mr. E. Ridley and Mr. B. Ambrose for assistance.

ELECTRONICALLY SCANNED SONAR IN THE INVESTIGATION OF FISH BEHAVIOUR

By Dr. V. G. WELSBY
Department of Electrical Engineering, University of Birmingham
AND
J. H. S. BLAXTER and C. J. CHAPMAN
Marine Laboratory, Aberdeen

RECENT preliminary tests with a new high-resolution sector scanning sonar have shown that equipment of this type has an important application to research on fish behaviour. The sonar set used was one designed at the request of the Marine Laboratory, Aberdeen, under a grant from the Development Commission and built in the Electrical Engineering Department of the University of Birmingham, in the course of a programme of research in underwater acoustics. Theoretical investigations of the problems involved and also a fuller description of the design and construction of the set are published elsewhere[1–6].

A carrier wave at 500 kc/s is modulated with 100 μsec pulses, corresponding to a range resolution of about 15 cm. The receiver has a nominal 3 db directional beam-width of $\pm \frac{1}{2}°$ and this is scanned over a sector of $\pm 15°$ within each pulse duration (that is, the scanning rate is 10,000/s). The receiving transducer array contains 30 lead–zirconate plates and the electronic scanning system has 30 signal channels, each associated with one element of the transducer array. The transmit array is arranged to radiate a peak within-pulse power of about 80 W into the water over the $\pm 15°$ scanned sector. Provision is made for the use of multiplicative signal processing which approximately doubles the angular resolution of the set, at the expense of some reduction in its effective maximum range. The output is presented on a plan position indicator (P.P.I.) display in which horizontal deflexion represents target range and vertical deflexion represents target bearing relative to the axis of the transducer array. With multiplicative processing, the set is capable of resolving objects at the same range when their angular separation is one degree.

The set was tested in a concrete tank holding sea-water and measuring 16 m × 13 m, the depth of water being about 1·6 m. The transducer was placed about 4 m from one end facing across the tank. The tank contained about 40 herring (25–30 cm long), five cod (63–69 cm), four skate (34–54 cm) and three dogfish (60–63 cm) and a number of small roundfish and flatfish. The fish had been

established in the tank as part of a project to test the reactions of commercial species to fishing gear, and especially to assess the herding effect of moving panels of netting at different light intensities. One of the problems had been to observe the extent of herding in low light intensities. Up to this stage, flash photography had been used; but it was found possible to observe individual fish so well with the scanner that a series of herding experiments was performed at dusk using a panel of white nylon netting with a mesh 22·5 cm², the behaviour of the fish being observed on the scanner.

Fig. 1 shows a typical frame from a ciné film of the P.P.I. display during such a herding experiment. Individual fish may be seen between the warps pulling the net. When any sonar is used in a confined space, such as a tank, spurious traces tend to be caused by acoustic reflexions from the boundaries of the medium, and also, as a result of multiple transmission path effects, the amplitudes of the wanted target echoes fluctuate rapidly with time. Even under these conditions, when the display was viewed directly, persistence of vision caused the wanted targets (in this case fish and the net) to appear as continuously moving spots on the screen which could easily be distinguished from unwanted 'noise', whereas much less information was contained in a single photograph. For this reason sketches have been used here (Fig. 2) to illustrate the observed results in more detail.

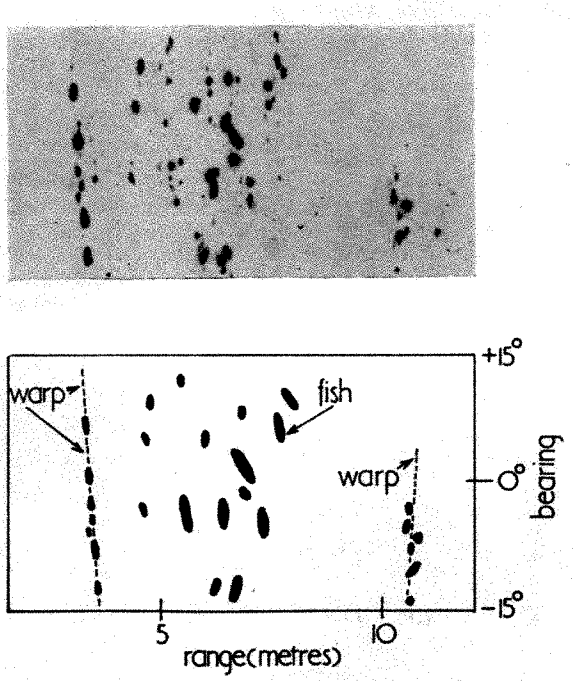

Fig. 1. Single frame from ciné film of sonar P.P.I. display, shown in negative form (with explanatory sketch below), taken during experiments on fish in a sea-water tank

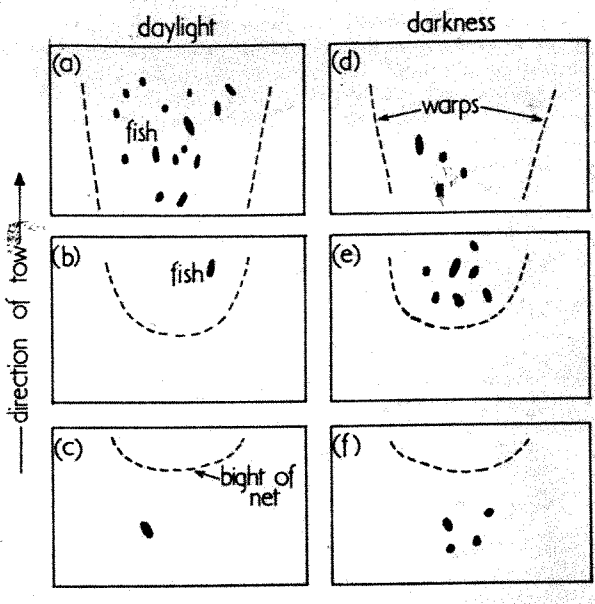

Fig. 2. Sketches of P.P.I. display showing typical results of herding experiments on fish in daylight and darkness

In Fig. 2, sketches (*a*), (*b*), (*c*) refer to daylight and (*d*), (*e*), (*f*) to darkness. The pattern of herding was found to alter as the light intensity dropped. Fig. 2 (*a*) shows a fairly large number of fish well in front of the net in daylight, being herded partly by the warps of the net. Fig. 2 (*b*) shows the bight of the net, with only one fish visible and Fig. 2 (*c*) shows a later stage in the haul, with one fish left behind (presumably having passed through the meshes of the net). At night (Fig. 2 (*d*)–(*f*)) the total number of fish herded became much reduced, the fish being much nearer the net and more passing through it.

Numerous experiments of this sort, using both the sonar and flash photography, showed that the pattern of herding changed at about 0·5 to 0·05 photopic lux. Clearly this is of importance in relation to the use of visual herding devices on trawls; these devices would become less effective at low light intensities.

The potential value of a high-resolution within-pulse scanning sonar for observing fish concentrations and movements in darkness or in turbid water can scarcely be over-emphasized, and the apparatus may well prove to have value for other types of observation in the dark.

MICRO-CULTURE OF HELA CELLS AND HUMAN EMBRYO LIVER ON POYTHENE DISKS

By HILLIARD FESTENSTEIN
South African Institute for Medical Research, Johannesburg

CULTURE of organs from chick embryos has been accomplished by squashing fragments of the organs to form thin films and sticking them to polythene surfaces with clotted mouse plasma. The technique was considered inapplicable to adapted cell lines and to embryo liver[1]. In certain experiments, the surface on which organ fragments and cell lines were cultivated consisted of reconstituted rat tail collagen[2,6]. This article describes a micropolythene technique for the cultivation of adapted cell lines and human embryonic tissues.

Polythene disks, 0·003 cm thick, and with a diameter of 1·5 cm were cut out with a metal punch and sterilized by immersion in ether[1]. 6–12 disks were then placed in a sterile Petri dish and on each disk was centred a sterile glass ring with an internal diameter of 0·7 cm, external diameter of 0·9 cm, and height of 0·65 cm (Fig. 1).

HeLa cells were propagated in Roux bottles in a growth medium consisting of 80 per cent 'Eagle basal special' medium and 20 per cent bovine serum. The 'Eagle basal special', prepared by the Poliomyelitis Research Foundation, Johannesburg, was an 'Eagle basic medium' in Hanks's base[2] containing 0·5 per cent (w/v) lactalbumin hydrolysate to which was added 1·9 mM *l*-arginine (thus bringing the *l*-arginine content up to 2 mM), 0·1 mM glycine and 0·1 mM *l*-serine; to this medium was added the crystalline sodium salt of penicillin *G* (200 u/ml.) and streptomycin sulphate (100 μg/ml.).

The cells were stripped with 0·25 per cent Difco trypsin in Dulbecco buffer[4], lightly spun down and re-suspended in the growth medium to a concentration of approximately $1·2–1·5 \times 10^4$ per ml. Of the suspension, 0·1 ml. was placed in each ring. Very little, or no leakage occurred at the junction of the polythene disk and glass ring. The Petri dish covered with lid was placed in a 6-in. vacuum desiccator and 90 per cent of the air was replaced with a mixture of 95 per cent nitrogen and 5 per cent carbon dioxide. The final gaseous mixture, therefore, contained 1–2 per cent oxygen. The jar was incubated at 35° C. Every 2–3 days the medium was pipetted off and replaced with a maintenance medium consisting of 95 per cent 'Eagle basal special' and 5 per cent bovine serum. The cells were examined by placing the polythene disks with the cells uppermost on a small drop of glycerol on a slide. A further drop of glycerol was placed on top of the disk, covered with a coverslip, sealed with two coats of nail varnish and examined under phase contrast illumination. Cultures of HeLa cells were successfully maintained in this manner for 10–14 days (Fig. 2).

The cultivation of human embryo liver was accomplished on polythene disks coated with a film of reconstituted rat tail collagen. Fresh rat tails were obtained from the Johannesburg City Health Department and stored at —20° C. The collagen was prepared in a manner similar to that described by Watson *et al.*[5], and Ehrmann and Gey[6]. After being soaked in 95 per cent alcohol for 10 min, the tail was successively fractured. As each 0·5 in. fragment was drawn away from the tail, the long, silvery tendon became stretched for 3–4 in. before the fragment came away, leaving stretched tendon still attached to the tail. The tendon was cut with sterile scissors and dropped into 10 ml. sterile, distilled water. All the tendon strands from one tail were teased apart and then transferred to a sterile 250-ml. centrifuge bottle containing 150 ml. of 1 : 1,000 acetic acid solution. This bottle was sealed and stored at 0°–4° C for 48 h during which time, as a result of further swelling of the tendon strands, the contents became transformed into 'a translucent jelly-like mass'. Following centrifugation at 4° C for 2 h at approximately 1,200*g*, 40 ml. of clear viscid fluid were transferred to McCartney bottles.

The acetic acid collagen solution was then dialysed against distilled water in an autoclaved 'Cellophane' bag at 0°–4° C. After 3 days the viscosity of the partially dialysed solution was markedly increased; it was then transferred to McCartney bottles and stored at 0°–4° C. Sterilized polythene disks with glass rings were placed in a standard Petri dish. Approximately 0·03 ml. of the viscous collagen solution was dropped into the centre of each ring without actually coming into contact with the sides of the ring. The Petri dish was left uncovered under an ultra-violet strip lamp while the collagen gelled. After 2 h, the collagen formed an invisible transparent film on the polythene disk and sterility was ensured at the same time. Approximately 0·1 ml. of the culture medium was then placed in each ring. Equilibration was allowed to occur; first for 1 h at room temperature and then overnight at 0°–4° C. The following morning, the medium was removed with a Pasteur pipette, and the collagen surface on the polythene disk was now ready for implantation. The Petri dishes thus prepared were sealed with parafilm and storable at 0°–4° C for at least 4–6 months.

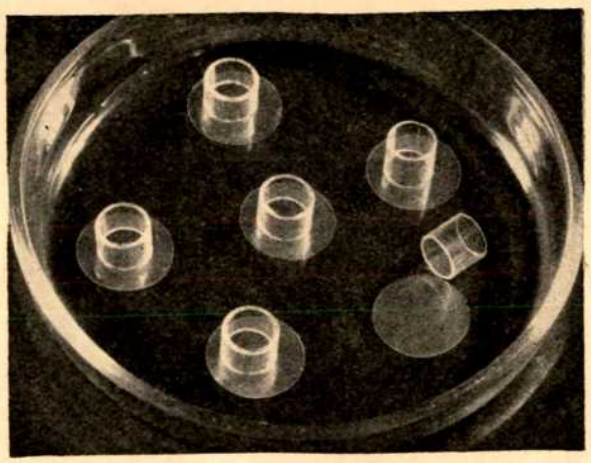

Fig. 1. Petri dish with polythene disks and glass rings in position

Liver tissue was obtained from 6–15 cm human fœtuses, partly from spontaneous abortions and partly from therapeutic terminations of pregnancy. Often 12 h elapsed before the material was received. The liver was minced moderately with fine-pointed scissors in a Petri dish containing 3–4 ml. Dulbecco buffer[4], washed 2–3 times with 5 ml. fresh Dulbecco buffer[4] to remove as much blood as possible, and then re-suspended in the culture medium. The tissue was then re-minced in order to obtain particles of less than 1 mm[3]. Approximately 0·1 ml. of the suspension was placed in each ring. The gaseous environment was the same as for the HeLa cells. Liver cells were

Fig. 2. HeLa cell culture, day 9, on untreated polythene disk; phase contrast illumination (×600)

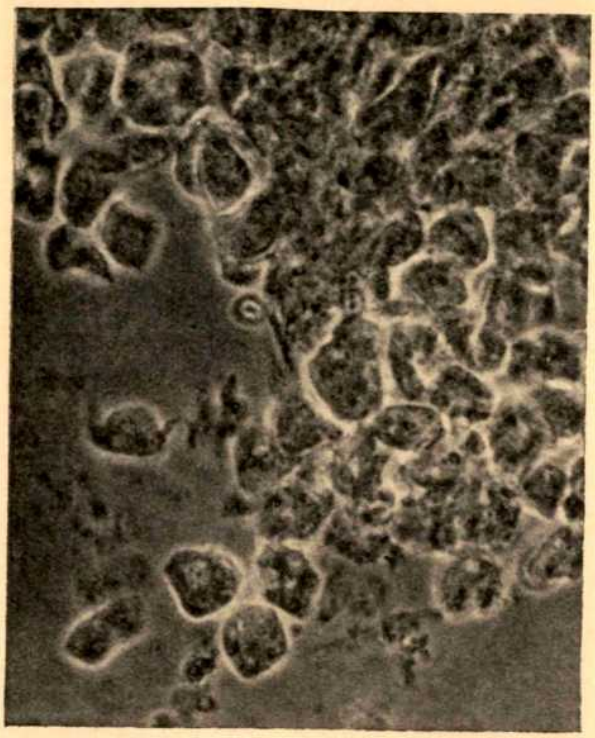

Fig. 3. Human embryonic liver explant day 2 on collagen coated polythene disk; culture medium: 80 per cent 'Eagle basal special', 20 per cent bovine serum, changed at weekly intervals; phase contrast illumination (×600)

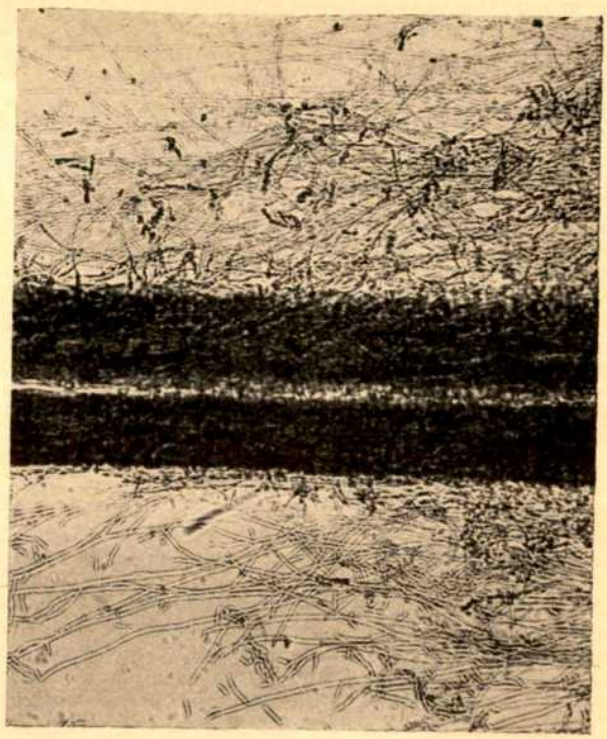

Fig. 4. Hair infected with dermatophyte; day 4 on untreated polythene disk showing mycelial outgrowth; phase contrast illumination (×120)

cultured in this way for at least 39 days (Fig. 3). Subculture of the cells has not as yet been attempted.

The microtechnique may also be successfully adapted to the growth of fungi. In this modification the polythene disk is floated on the surface of sterile saline contained in a screw-capped jar, 3 cm in diameter. Glass rings are not used; 0·05 ml. of a suspension of the infected material in an appropriate fungus medium is seeded directly on to the untreated polythene surface. Several such jars can be prepared from each specimen and examined at regular intervals. An example of such a culture is illustrated in Fig. 4, in which a dermatophyte may be seen growing out of an infected hair after 4 days incubation at room temperature.

I thank Dr. V. Bokkenheuser for criticism, Miss M. A. S. Birrell for assistance, Mr. M. Ulrich for the photographs, the director of this Institute, Dr. J. H. S. Gear, and Dr. P. D. Swanepoel, superintendent of the South Rand Hospital, Johannesburg, for facilities granted.

OXYGEN IN THE GAS VACUOLE OF THE RHIZOPOD PROTOZOAN, *ARCELLA*

By ANNA CICAK, J. J. A. McLAUGHLIN and Prof. J. B. WITTENBERG
Department of Physiology, Albert Einstein College of Medicine, New York 61 and the Haskins Laboratory, New York

THE rhizopod protozoan *Arcella* is perhaps unique in repeatedly forming large gas-filled vacuoles in its cytoplasm. These gas vacuoles, first observed by Perty[1], attracted the attention of Engelmann[2,3], and were investigated by Bles[4]. F. Gowland Hopkins and the late D. Keilin, in their preface to Bles's posthumously published paper, state: "we believe . . . that it was Dr. [J. S.] Haldane's firmly expressed belief in the great biological importance of gas production as observed in Arcella which, more than anything else, urged Bles to his experimental study of the phenomenon".

Bles's many ingenious experiments with vital dyes led him to believe that the gas in the vacuole was oxygen produced by the chemical action of 'oxidases'. It is perhaps difficult to-day to reconstruct the full impact of these experiments; but both J. S. Haldane and D. Keilin, who followed Bles's work closely, felt that he had convincingly shown that the gas was oxygen (Keilin, D., private communication). However, certain identification of the gas ultimately must rest on direct analysis, and Bles's monograph[4], edited after his death and thirteen years after the work was done, presents only a single experiment on identification of the gas by chemical means. He crushed *Arcella* containing gas vacuoles in a solution of potassium hydroxide and concluded: "The experiments with caustic potash solution show not only that the gas in

the vacuole is not CO_2 but that it must be one of the gases forming the bulk of air because saturation of the solution with air increased the time taken to dissolve the gas from the vacuole. This sequence of experiments points again to the gas being oxygen . . . ".

We believe that Bles failed to appreciate the speed with which gases dissolved in the potassium hydroxide solution invade a very small bubble and replace the gases initially present. In fact, Krogh[5] had found that because of this difficulty the practical lower limit for the size of the bubble that could be analysed when freely suspended was 0·01 μl., 100 times larger than the bubble from *Arcella*. We have observed that the bubbles, formed from the vacuole contents when *Arcella* are crushed in alkaline pyrogallol, often enlarge abruptly before diminishing gradually. The abrupt enlargement points to another difficulty to be circumvented if a meaningful analysis is sought[6]. Two solutions of different concentration, each saturated with air, become greatly supersaturated when mixed and will give off gas through any available surface. In this case, mixing of adhering culture medium or protoplasmic water with the strong potassium hydroxide may double the local gas tension. For analysis of the vacuole contents the gas bubble must be protected from invasion by gases in the environment.

For a brief period cultures of *Arcella vulgaris* which had been established some two years earlier for the purpose of investigating gas vacuole formation had many individuals containing gas-filled vacuoles, Fig. 1. The cultures were maintained with alternating periods of light and darkness; by chance the light period fell during the night. From 2100 to 0400 h about one-third of the animals contained a gas vacuole at any one time, and since the life-time of a vacuole is short and new vacuoles were continually forming in quiescent animals, most individuals must have formed vacuoles many times during the night. The animals were remarkably uniform in size, the test was 170μ in diameter; the protoplasm, not completely filling the test, averaged 145μ diameter. The gas vacuoles ranged from 30μ to 60μ diameter, their volume being 2 to 8×10^{-5} μl., 5–10 per cent of the volume of protoplasm.

To analyse the gases of the vacuole, individuals were transferred to a glass slide together with a minute droplet of culture medium, and the diameter of the vacuoles estimated by comparison with a grid mounted in the microscope ocular. A drop of potassium hydroxide solution (50 g in 100 g water) which had been boiled and evacuated to remove gases or a drop of potassium hydroxide–pyrogallol solution (10 g pyrogallol dissolved in 100 ml. of the degassed potassium hydroxide solution and once again degassed *in vacuo*) was placed over alternate animals, and a cover-slip was dropped on the pool of reagent so that the violent currents resulting swept the residual culture medium from the animal. It was essential that the culture medium be completely removed, and accordingly the success of this manœuvre was verified in separate experiments with droplets of indian ink. As soon as the animal could be found in the microscope field (usually after 20 sec), the vacuole diameter was once again noted and observed until it disappeared. On contact with the potassium hydroxide solution the vacuole lost its complex shape and became spherical, apparently with some shrinkage whether pyrogallol was present or not.

The rate of loss of gas from the vacuole will be governed by the rate of outward diffusion across the now dead but still intact protoplasm, and this in turn will depend on the partial pressure difference for each gas between the bubble and the potassium hydroxide solution immediately adjacent to the animal. Because the solution is viscous and unstirred, and because the solubility of gases in the concentrated potassium hydroxide is very limited, gases diffusing from the animal will diffuse only very slowly into the bulk of the solution, but will tend to remain in a thin

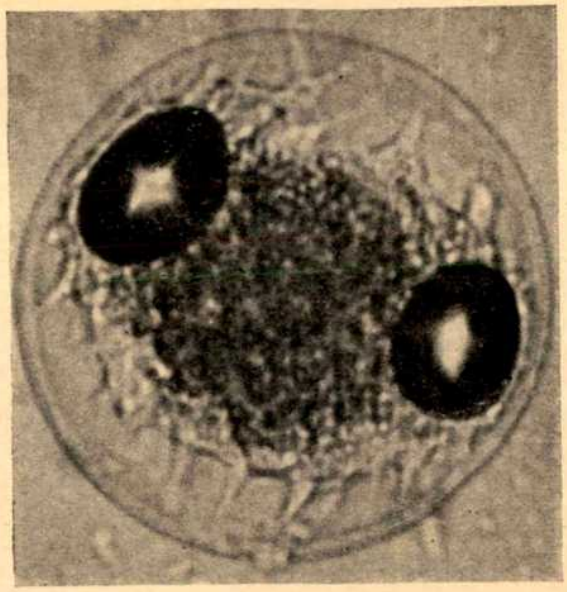

Fig. 1. Photograph of an *Arcella* containing two gas vacuoles

shell of fluid surrounding the animal. The gases accumulating in this very thin layer of potassium hydroxide solution, because of their limited solubility in that solution, exert substantial partial pressures which oppose further loss of gas from the vacuole. If the potassium hydroxide solution contains pyrogallol, oxygen leaving the animal is instantaneously consumed, the oxygen tension adjacent to the animal remains zero, and the rate of oxygen loss from the bubble should be greater than for other gases.

The rates of shrinkage of the gas bubbles in: (*a*) animals treated with potassium hydroxide solution; (*b*) animals treated with potassium hydroxide–pyrogallol solution are compared in Fig. 2. The initial bubble volume was taken as the volume 1 min after adding the reagent, since earlier readings were difficult and the vacuole in the living animal has a complex shape. The final volume was arbitrarily taken 5 min after adding the reagent. (The results are not different if the final volume is taken as the volume at 3 min). Fig. 2 is a frequency diagram relating number of animals to fractions of the initial gas volume absorbed during this interval. Clearly the bubble tended to persist in animals flooded with potassium hydroxide solution and tended to disappear in animals flooded with potassium hydroxide–pyrogallol solution. Application of the median test[7] confirms that the two groups, *a* and *b*, are drawn from populations having different medians (at the 5 per cent confidence level).

Oxygen, we conclude, makes up the largest part of the gases present in the gas vacuole of *Arcella*.

The volume of large gas vacuoles may be as much as 10–15 per cent of the protoplasmic volume. Since the amount of oxygen dissolved in protoplasm is only 0·6 volume per cent, the oxygen filling the bubble must be brought from outside the animal. To understand this transport one turns to the observations of Bles and, in his words (*loc. cit.*, p. 556): "An arcella which had formed five large gas-vacuoles . . . was crushed in the usual way, and it was found that the five bubbles pressed out did not coalesce to form a single bubble: in fact, two of them were caught inside the broken test; of the three which escaped, two in the course of the first minute after crushing were absorbed by protoplasm adhering to the coverglass. The third, instead of disappearing, began rapidly to expand. It was measured by the eye-piece micrometer one minute after crushing; four minutes after crushing it had grown $1\frac{2}{3}$ times its diameter when first measured. It then steadily increased in size for 1 hr. 42 min., during

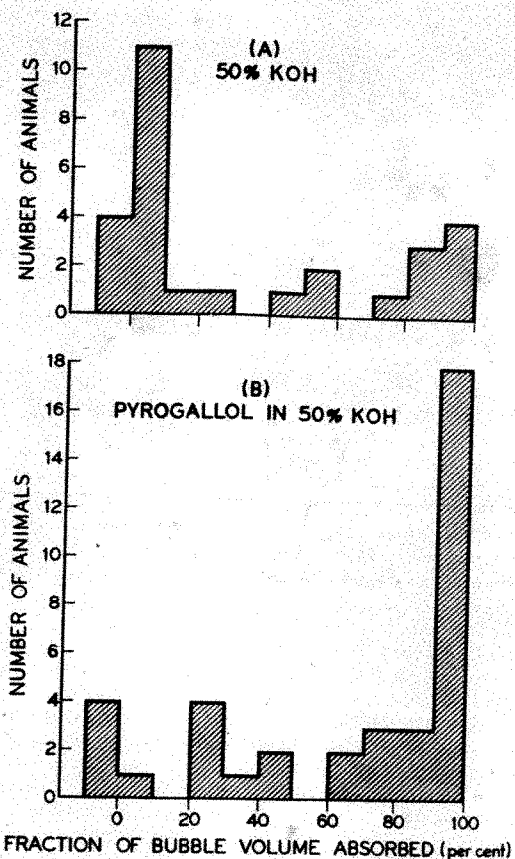

Fig. 2. Frequency diagram relating the numbers of animals to the fraction of the bubble volume (measured 1 min after adding the reagent) which is absorbed during the ensuing 4 min

which it was measured every few minutes, and found every time to be growing in diameter. At the end of this period it had grown to 5½ times its original diameter, its volume having increased, assuming that temperature and pressure had remained constant, to [155] times its original volume". Also: "A further crushing experiment was made in order to test the action of peroxide of hydrogen on a fragment of protoplasm containing a minute remnant of a gas vacuole. After crushing, a piece of the protoplasm was found containing a gas vacuole which was watched and seen to be shrinking. Eight minutes after crushing a weak solution of peroxide of hydrogen (about 1 per cent) was run in and within thirty seconds the size of this gas vacuole was measured. One minute later the diameter was six times greater and the vacuole continued to grow. The vacuole had increased in diameter about ninety times in forty-three minutes. . . . The gas in both experiments may be the product of catalase action upon a peroxide formed by the oxidase activity of the cell. In the peroxide experiment there can be little or no doubt that the gas in the vacuole is due to the reduction of the peroxide of hydrogen, and the growth of the gas-vacuole in the peroxide experiment corresponds exactly with the spontaneous growth of the gas vacuole in the crushing experiment described above. The difference between the two cases is that the peroxide of hydrogen was supplied in one of them, and in the other the peroxide was present in the protoplasm".

The work recorded here establishes by direct analysis that the gas brought into the vacuole of *Arcella* is predominantly oxygen. Presumably oxygen from the medium is reduced to hydrogen peroxide, diffused in this form and, after transport, is decomposed to oxygen, probably by catalase. The morphology of the specialized cytoplasm adjacent to the bubble is being studied in collaboration with D. E. Copeland and A. Fitzjarrell of Tulane University. The technique for culturing *Arcella* will be described elsewhere.

This investigation was supported by U.S. Public Health grants *RG* 7022 and *H* 3719 from the Division of General Medical Sciences and the National Heart Institute at the National Institutes of Health. One of us (J. B. W.) was supported by a U.S. Public Health Service research career programme award (*SF* 57) from the National Heart Institute of the National Institutes of Health.

INDUCTION OF BUDS ON OLDER LEAF PRIMORDIA IN FERNS

By Dr. ELIZABETH G. CUTTER and Prof. C. W. WARDLAW

Department of Botany, University of Manchester

SEVERAL recent investigations of morphogenesis in ferns have yielded information about the developmental potentialities of leaf primordia. For example, in *Dryopteris dilatata* (Hoffm.) A. Gray (*D. aristata* (Vill.) Druce) it has been shown that leaf sites and very young leaf primordia are initially capable of development either as leaves or as buds, since they can be induced to develop as buds if isolated from the shoot apex[1–3]. After a certain stage of development, coinciding with the formation of the lenticular leaf apical cell, the primordium can no longer be induced to develop as a bud but even when isolated from the shoot apex will develop as a normal, dorsiventral leaf primordium. Occasionally, small buds are formed in association with such isolated older leaf primordia, some distance up from the base of the petiole[4].

In *Osmunda cinnamomea* L., leaf primordia excised from the subtending shoot after a certain stage of development are capable of developing into small but morphologically normal fronds when grown on a comparatively simple nutrient medium[5], but some of the youngest primordia, similarly treated, give rise to shoots and later complete plants[6]. The nine youngest leaf primordia of *O. cinnamomea* are considered to be capable of development as shoots[7], whereas in *Dryopteris* only the three youngest visible primordia have this potentiality[3]. In recent experiments[8], it has been shown that the halves of leaf primordia of *O. cinnamomea* which were bisected and grown in culture could regenerate either as leaves or shoots, according to the age of the primordia and other conditions. The occurrence and development of buds in

ferns have been surveyed by several of the older morphologists, notably Bower[9]. In *Dryopteris* buds are typically formed in interfoliar positions; where the shoot apex is intact, buds are not usually formed in the apical or immediately sub-apical regions.

With this background of information, it was considered that experiments involving various incisions of older leaf primordia of *Dryopteris dilatata* (those known to be determined as leaves) might induce interesting new morphogenetic developments, both foliar and cauline, and at the same time yield information about the distribution of meristematic, or potentially meristematic, tissues within the leaf and their control during growth and development. In one series of experiments, leaf primordia of *D. dilatata* ranging in age from the third youngest, P_3, to P_{20}, the majority being from P_5 to P_{15}, were either radially bisected with a microscalpel or punctured with a tungsten needle; some of the primordia in each group were also isolated from the shoot apex. Usually only the apical cell of the leaf primordium was punctured, but the resulting necrosis often spread to neighbouring cells; damage from the bisecting incision also spread a little. The regions of leaf tissue on either side of the damage resulting from the puncture or bisection (half-primordia) can regenerate either leaf primordia or buds. In all the experimental treatments of older leaf primordia, no evidence was obtained of bud formation as a result of a transformation of the leaf apical meristem. The results of these experiments, in terms of the fate of the half-primordia, are shown in Table 1, from which a few anomalous results, to be described in a later paper, have been omitted. Both in Table 1 and afterwards, all foliar developments are termed 'leaf'; we realize, however, that some of these developments may be of pinna nature. In Table 1 the category 'leaf + bud' comprises regenerated leaves which bore buds on the petiole; these were obtained both from bisected (Fig. 1) and from punctured primordia (Fig. 2).

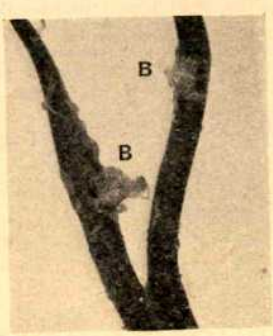

Fig. 1. Part of the petioles of the two leaves obtained from P_{20}, which was bisected and isolated from the shoot apex. Buds (*B*) are borne on both petioles. Eleven weeks after treatment. (All photographs by Mr. G. Grange.) (Same scale)

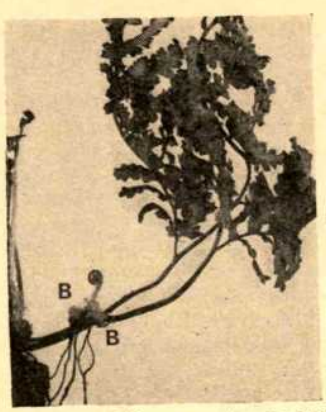

Fig. 2. A leaf primordium which was punctured and isolated. Fifteen weeks later, two expanded leaves had been formed, and two buds with roots were present on the petiole. (× 0·5)

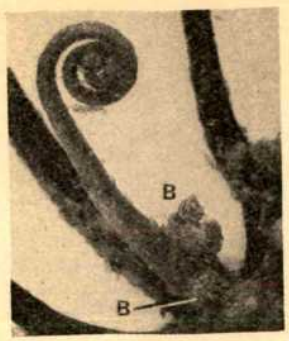

Fig. 3. P_{12}, isolated from the shoot apex by an adaxial incision, developed as a normal, dorsiventral leaf primordium, with a bud (*B*) on one flank and a smaller bud (arrowed) near the base of the other flank. Eleven weeks after isolation. The formation of two buds was unusual. (× 2)

Growth in general, and especially bud growth, was greatly stimulated by isolation from the shoot apex (Table 1). Where buds occurred on primordia which were not isolated, their appearance was belated, occurring 2 months or more after the experimental treatment, by which time the primordia were at some distance from the shoot apex.

Seventeen leaf primordia ranging in age from P_5 to P_{19} were isolated from the shoot apex without further treatment, their apices remaining intact. Of these, all developed as dorsiventral leaf primordia of approximately normal size, but 10 bore buds laterally or adaxially on the petiole (Fig. 3). These results were in accordance with previous findings[4].

Table 1. Effects of Puncturing or Bisecting Leaf Primordia, With or Without Isolation

Treatment	No organized development	Result: Leaf	Leaf + bud	Bud	Total
Punctured					
Not isolated	17	5	2	1	25
Isolated	25	14	12	24	75
Bisected					
Not isolated	26	5	6	—	37
Isolated	15	7	16	22	60

In another series of experiments, either one or two small, approximately horizontal incisions were made laterally into the subdistal, that is, presumptive petiole, region of leaf primordia ranging in age from P_9 to P_{22}. Such incisions partially isolated portions of the marginal meristem from the influence of the leaf apex. Some of the primordia were also isolated from the shoot apex. The results are summarized in Table 2. In this case, the category 'leaf and bud' implies that both organs were formed, separately but in proximity, in relation to the incisions (Fig. 4).

In most instances the outgrowths were formed below the cuts, often between them if there were two cuts, and sometimes rather adaxially. In a few specimens, not included in Table 2, meristematic outgrowths were induced on the opposite flank of the petiole to the one which had in fact been incised. In another experiment, incisions similar

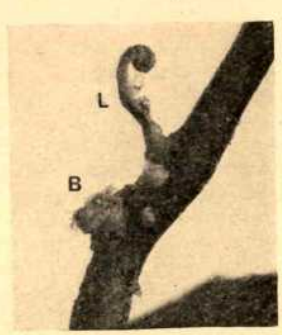

Fig. 4. The petiole of P_{15}, given two cuts across the marginal meristem and isolated from the shoot apex, now shows a bud (*B*) and a leaf primordium or pinna (*L*) formed in relation to the cuts. Thirteen weeks after treatment. (× 2)

Table 2. Effects of Lateral Incisions on Leaf Primordia, With or Without Isolation

Treatment	No organized development	Result Leaf	Leaf and bud	Bud	Root	Total
Lateral incisions						
Not isolated	31	—	1	4	1	37
Isolated	13	—	1	10	—	24

to these were made into the abaxial side of the primordia; such growths as were obtained occurred adaxial to these cuts, not between or directly below them.

Meristematic activity was induced not only in primordia isolated from the shoot apex, but also in those only given lateral incisions. Occasionally two outgrowths were formed below the cut, an upper leaf primordium (or pinna) and a bud below this. Whereas the cuts were originally made fairly close to the tip of the primordium, the ultimate position of the outgrowths was fairly low down on the petiole (Figs. 5 and 6). It appears, therefore, that the incisions were made in and the meristems grew out from that part of the fern petiole which does not normally undergo much increase in height[10].

In 11 primordia, ranging in age from P_{10} to P_{19}, vertical incisions were made abaxially in the base of the petiole, with the intention of disrupting the incipient vascular

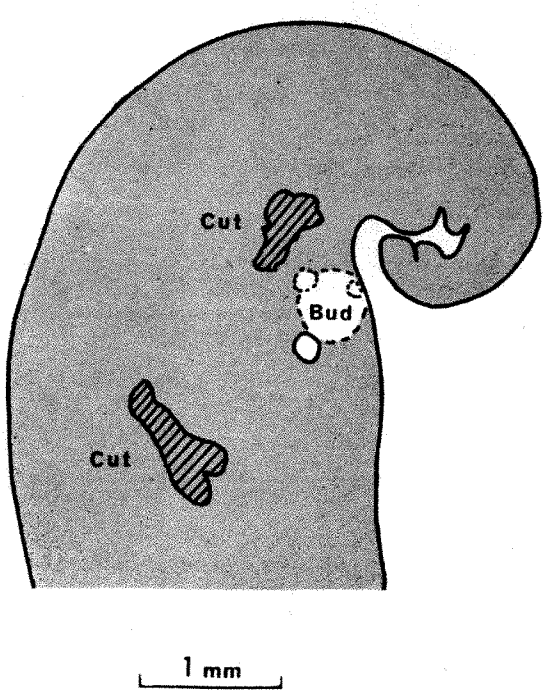

Fig. 5. A bud has formed between and slightly adaxial to two cuts (now opened out and visible as necrosed tissue, cross-hatched) across the marginal meristem of P_{12}, which was also isolated from the shoot apex. Seven weeks after treatment. (see Fig. 6)

Fig. 6. P_{12} with the bud shown in Fig. 5, four weeks later. The leaf tip has grown on considerably. (× 2)

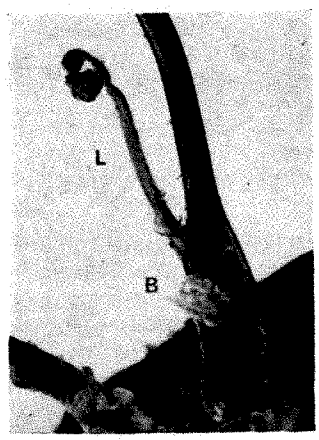

Fig. 7. P_{11}, split abaxially near the base of the petiole and isolated from the shoot apex, bears a leaf primordium or pinna (L) on one flank of the petiole, and a bud adaxially, above the archway formed by the split. Thirteen weeks after treatment. (× 2)

tissue therein. Seven of these primordia were also isolated from the shoot apex. Of the 4 primordia which were not isolated, one had a double tip, although there was no evidence of apical damage; the other 3 showed no response to the slit. Of the 7 isolated primordia, 4 gave rise to buds, 2 of which were formed more or less directly above the archway resulting from the split; one gave rise to a leaf primordium or pinna on one flank, with a bud above the archway (Fig. 7), and 2 showed no response.

In all these experiments, presumptive petiolar regions were induced to grow out as organized meristems of various kinds, indicating that lateral and adaxial regions of leaf primordia of *Dryopteris* are, under certain circumstances, capable of organogenic developments which they do not normally undergo. This was usually effected by isolating them from the leaf apex, or by destroying this. Possible direct or indirect effects of wound hormones may to some extent be involved. Isolation of older leaf primordia from the shoot apex, that is, in addition to the other treatments, typically resulted in the induction of a higher proportion of organized outgrowths.

Collectively, these results suggest that the apex of the leaf primordium of *Dryopteris* exercises a controlling effect on the tissues below it akin to that of the shoot apex on its lateral meristematic tissues. Growth centres in the marginal meristems grow out as pinnæ, just as leaf primordia originate from growth centres in the shoot apical meristem: but other regions of the leaf do not grow out in the normal development, although these experiments indicate that they can be induced to do so, not only as foliar organs but as buds. Thus the organized leaf apical meristem, of which the lenticular apical cell is an integral component, seems to determine the form and structure of the leaf. Notwithstanding the excellent classical studies of leaf apical and marginal meristems in ferns, a fuller investigation of the distribution of these meristematic or potentially meristematic tissues is now seen to be required. Discussion of the various problems which these new discoveries evidently raise, and also of the cognate findings of contemporary workers, will be held over until the anatomical studies of our experimental materials, now in progress, are completed.

ASTROPHYSICS

Bolometric-Correction and Effective-Temperature Scale

In recent years the application of high-speed digital computers to problems in theoretical astrophysics has combined with fundamental research in nuclear physics and solar convection to achieve considerable understanding of the physics of not only stellar interiors but also stellar evolution. The connecting link between this increasingly elaborate theory and the corresponding ensemble of observations is the scale of bolometric-corrections (*B.C.*) and effective-temperatures (*Te*).

Much of the early theoretical work dealt with luminosities and effective-temperatures in a range where the uncertainties in these scales have been generally felt to be less severe than uncertainties stemming from the assumptions inherent in the stellar models. The sources of uncertainty in the *B.C.* and *Te* scales have been reviewed by Popper[1], whose arguments will not be reproduced here. The scales are in all ranges in a position to benefit from modern methods of radiometry, applied both from ground observatories and spacecraft, and from a vastly improved knowledge of the transmission of the atmosphere.

In particular, however, a stellar model of 15·6 solar masses has now been constructed by Hayashi and Cameron[2]. The initial and final portions of the evolutionary track for this supergiant can only be related to observation by way of an educated guess. The early supergiant phase requires the *B.C.* and *Te* from model atmospheres, the empirical scales being precluded by the atmospheric ozone cut-off. The *M* supergiant phase requires that an already poorly determined empirical scale for late type stars, which definitely suggests a dispersion due to luminosity class that cannot be adequately accounted for because of a paucity of data, must be extrapolated.

Work is at present being carried out to alleviate this situation, but which, unfortunately, will not be available for some time. In the meantime this communication is an attempt to compile the most reliable set of *B.C.*'s and *Te*'s from the literature; which scales will be used in a forthcoming investigation of the region surrounding *h* and χ Persei.

A number of recently proposed *B.C.* and *Te* scales have been drawn in Figs. 1 and 2 together with mean relations extracted by me from pure data-point plots also recently published. I shall now briefly review the source of each in chronological order.

(1) Arp[3] has conducted the most recent review and compilation which extends over the entire observational range of temperature. Earlier than *B*2, the *B.C.*'s have been obtained from the prediction of *B.C.* and *Sp* from the model atmospheres of Underhill and McDonald. Later than *B*5 the *B.C.*'s are from the early comparison of the radiometric magnitudes of Pettit and Nicholson with the corresponding photovisual magnitudes. For the *Te* scale model atmospheres are again used early through *B*2. For later stars the scale is based on a colour-temperature-interpolation by six-colour photometry between the real *Te*'s of the Sun, β Aurigæ (eclipsing binary), and those based on interferometric diameters of bright giants and supergiants (Pease). The real *Te*'s in each case involve the angular diameter (either directly measured or inferred from other measurements) and the *B.C.*'s of Pettit and Nicholson.

(2) Popper[1] has revised the *B.C.*'s chiefly by changing the argument of the scale from *Sp* to $(B-V)_0$ (photoelectric), and returning to the original radiometric data of Pettit and Nicholson and subtracting photoelectric *V* magnitudes. The radiometric data of Emberson with an adjusted zero-point was also used. For the effective-temperatures, beyond the improvement afforded by the revised *B.C.*'s, an additional fundamental datum is

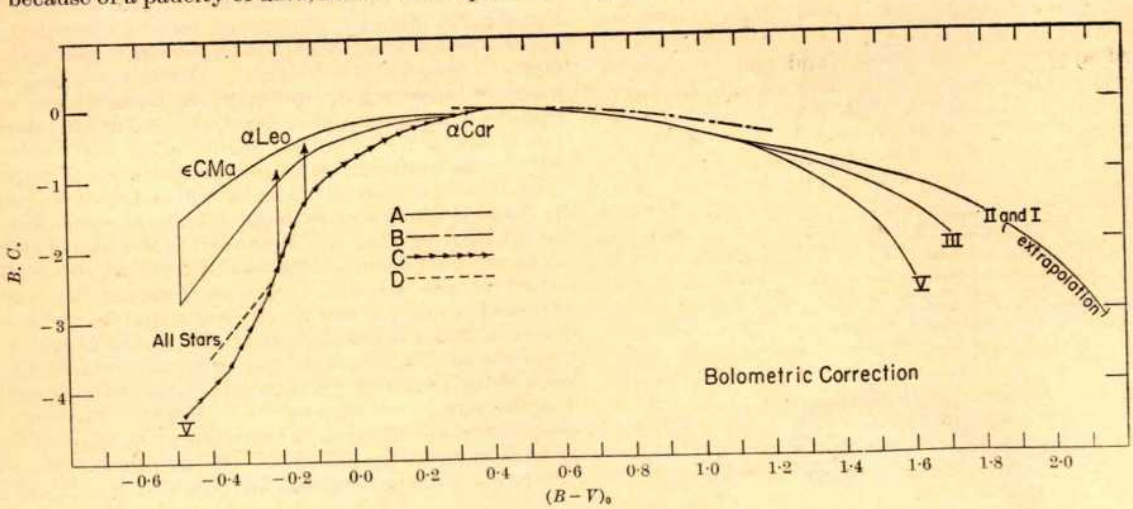

Fig. 1. Bolometric-correction Scales proposed by Various Authors

The solid curve (*A*) is the mean relation for Popper's analysis. The centre-lined curve (*B*) is Oke's. The arrow-head curve (*C*) is due to Arp. The dashed curve (*D*) is Schmalberger's. The recommended relation is given by the following table

$(B-V)_0$	Class I	Class II	Class III	Class IV	Class V
−0·48 to −0·40	*C* + 0·40	*C* + 0·40	*C* + 0·40	*C* + 0·40	*C* + 0·40
−0·40 to −0·22	*D*	*D*	*D*	*D*	*D*
−0·22 to 0·30	*C*	*C*	*C*	*C*	*C*
0·30 to 0·40	*B*	(*B* + *C*)/2	*C*	*C*	*C*
0·40 to 1·20	*B*	(*B* + *A*)/2	*A*	*A*	*A*
1·20 to —	*A* + 0·23	*A* + 0·23	*A*	*A*	*A*

The curves in the figure are labelled according to luminosity class.

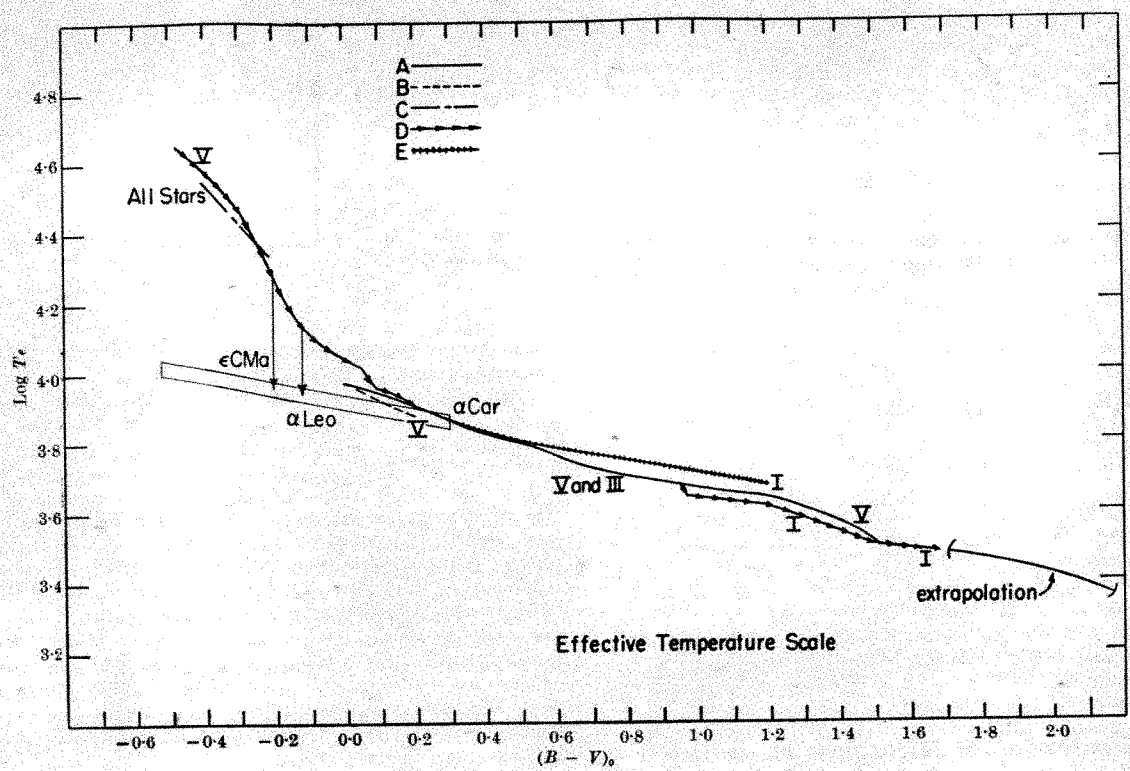

Fig. 2. EFFECTIVE-TEMPERATURE SCALES PROPOSED BY VARIOUS AUTHORS

Solid curve (*A*), Popper; dashed curve (*B*), Bless; centre-lined curve (*C*), Schmalberger; arrow-head curve (*D*), Arp; and lazy-*T* curve (*E*), Oke. The recommended relation is given by the following table

$(B-V)_0$	Class I	Class II	Class III	Class IV	Class V
−0·48 to −0·40	$D-0{\cdot}036$	$D-0{\cdot}036$	$D-0{\cdot}036$	$D-0{\cdot}036$	$D-0{\cdot}036$
−0·40 to −0·22	C	C	C	C	C
−0·22 to 0·00	D	D	D	D	D
0·00 to 0·20	$(B+A)/2$	$(B+A)/2$	$(B+A)/2$	$(B+A)/2$	$(B+A)/2$
0·20 to 0·30	A	A	A	A	A
0·30 to 1·20	E	$(E+A)/2$	A	A	A
1·20 to 1·30	$D+0{\cdot}061$	$(D+A)/2+0{\cdot}030$	A	A	A
1·30 to —	$D+0{\cdot}061$	$(D_I+D_V)/2+0{\cdot}030$	D	D	D

The curves in the figure are labelled according to luminosity class.

admitted due to the measurement of the diameter of Sirius by Hanbury Brown and Twiss. Popper suggests further that empirical *B.C.*'s be used no earlier than *FO* because of atmospheric extinction and relies on model atmosphere predictions in the earlier range (Hunger, Osawa, Saito, and Underhill and McDonald).

(3) Schmalberger[4] gives *B.C.*'s and *Te*'s for *O* and *B* stars from the model atmosphere computations of *Sp*, *B.C.*, and *Te* from Pecker, Underhill, McDonald, and Traving.

(4) Bless[5] has made photoelectric spectrum scans of *A V* stars and obtained the *Te* on the basis of several predicted (model atmospheres) and measured criteria. The criteria chosen were the Balmer discontinuity and the monochromatic magnitude differences: $m(\lambda 4{,}600)-m(\lambda 4{,}190)$; $m(\lambda 5{,}600)-m(\lambda 4{,}400)$, and $m(\lambda 6{,}000)-m(\lambda 5{,}000)$.

(5) Oke[6] has obtained photoelectric spectrum scans for various phases throughout the light cycle of δ Cephei. With concurrent high-dispersion spectrograms he has measured the line-blanketing at various wave-lengths and corrected the scans to obtain the true continuum as a function of phase. He has fitted model atmospheres to each continuum and thereby obtained the *Te* and *B.C.* as a function of phase hence $(B-V)_0$. These have then been recorrected for the blanketing-effect, thus providing *Te* and *B.C.* versus $(B-V)_0$ for true stars rather than their continua.

The reader is referred to the foregoing five authors for reference to authors referred to by them.

In the present compilations the argument has been converted from *Sp* to $(B-V)_0$ whenever necessary. The *Sp* versus $(B-V)_0$ relation used was that given by Arp[3] except for *O* stars and class I stars where the relation was derived from results in *h* and χ Persei to be published later.

I have indicated in the figure captions what I feel to be as reliable a choice of scales as is possible at the present time.

Ultra-violet observations already published[7] show such disparity with model atmospheres that their effect on the *B.C.* and log *Te* scales can scarcely be evaluated until the ultra-violet spectrophotometry is successfully carried out on *O* stars and in addition pushed farther toward the X-ray region. Nevertheless, a crude indication has been obtained of the correction to be applied to the selected curves of Figs. 1 and 2. The fluxes of ε *CMa*[7] and α Leo[7] have been extrapolated by eye to zero wave-length under the assumption that the second derivative of the energy distribution curve is no larger in this region than in the observed portion of the ultra-violet. Both this energy distribution and that of the comparison model-atmosphere[7] were planimetered for each star. Their ratio provided a Δ *B.C.* $=4$ Δ log *Te*. These are shown in Figs. 1 and 2 as vectors. Schematic indications of what one might expect as the *B.C.* and log *Te* scales of the future are shown by the blocked-in areas in the early parts of the Figs. Agreement is produced between these prognostications and present scales at $(B-V)_0=0{\cdot}30$, since Stecher and Milligan's[7] ultra-violet observations of α Car are in agreement with theory.

In summary, I have presented *B.C.* and *Te* scales which I feel reflect the most recent theory and data. However, it must be recognized that crucial observations have not

yet been carried out using modern techniques. When improvements afforded by: (1) the use of detectors of increased accuracy and sensitivity extending farther into the ultra-violet to X-ray region and into the 2–8μ infra-red; (2) satellite-based observing stations; (3) reliable absolute calibrations of detector responsivities; (4) interference filters which enable one to make Earth-bound observations only through atmospheric windows, the extinction law of which is properly evaluated, are incorporated in the final analysis, we must be prepared to accept revisions in *B.C.* which *may* reach tens of per cent for intermediate spectral types to nearly orders of magnitude for early *O* and late *M* stars.

Concentration of Nightglow H_α-emission to the Ecliptic and the Radial Velocities of this Line

During the winter of 1962–63 I examined the distribution of H_α-intensity over the night sky. A Fabry-Pérot étalon was used with a spacing of 0·3 mm and reflexion coefficient 0·91 at H_α. An interference filter of 30 Å half-width was used as premonochromator. A contact image intensifier was used for registering the fringes. The whole system was installed on a small equatorial mounted in a tube in which temperature was controlled. The observations were made at the high-altitude station of the Sternberg Astronomical Institute ($\varphi = 44°$, $h = 3{,}000$ m) near Alma-Ata. One-hour exposure was sufficient to record H and OH fringes at any point of the sky, including the zenith.

The distribution of the night-glow H_α-emission shows a considerable concentration to the ecliptic and to the Sun. If the H_α intensity in the antisolar point is taken as 1, the intensity on the ecliptic at elongations 70°–90° from the Sun reaches 4–5 (Fig. 1). The distribution is markedly asymmetrical, the morning intensities being greater. The H_α intensity distribution across the ecliptic at the elongation of 90° (morning side) is shown in Fig. 2. The intensity of H_α in other point of the night sky at the same zenith distance, but far from the ecliptic, shows no enhancement. During the observations the regions close to the Sun were situated far from the Milky Way; its position is marked on Fig. 1. The H_α-intensity at 70°

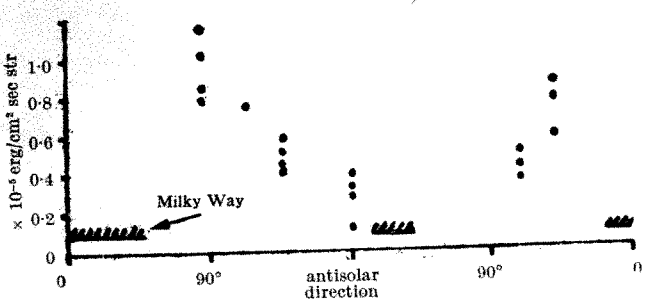

Fig. 1

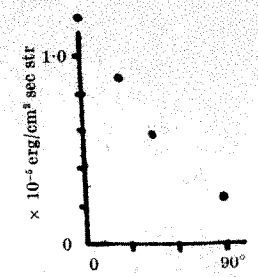

Fig. 2

elongation is greater than in a region of Milky Way without emission nebulæ.

An attempt was made to measure the radial velocities of H_α at 90° elongations. The dispersion of the monochromator used was 2 Å/mm for the fringe measured; the width of the H_α-line in the night-glow does not exceed 0·3 Å. A collimating lens of 2-m focal length sends into the apparatus the image of a white cross centred on the axis and illuminated by an H discharge tube. On the plate, points from the calibration cross were superimposed on the night sky fringes. The width of the line being 0·3 Å, a shift of 0·1 Å, corresponding to a radial velocity of 4·5 km/sec, could be easily detected. The measurements gave no certain evidence of relative shift of the two lines and the night-glow H_α radial velocity at 90° elongations must be less than the aforementioned value. In the antisolar direction a positive radial velocity was observed but not very certainly.

The small radial velocity and narrowness of the night-glow H_α line are strong arguments for its atmospheric origin. The observation can be fitted with the following model: neutral hydrogen forms a disk in the ecliptic plane 5,000 km thick and extended up to 3,000 km in the evening and to 10,000 km in the morning. During the night the hydrogen exosphere becomes denser as shown in a recent paper of Donahue (private communication). At sunrise intense dissipation begins, but the density remains high enough during several hours. It is a plausible explanation of the east–west asymmetry of the H_α night-glow. Such measurements can be used for determining the density of the exosphere, which depends strongly on the temperature of the thermopause. An interesting observational problem is the interaction of the Doppler-shifted Fraunhofer line in the zodiacal light and the H_α night-glow when observed with finite spectral resolving power. We have perhaps observed a darkening of the emission line at elongation near 90° due to such interaction.

RADIOPHYSICS

21-cm Absorption of the Radiation from 3C273

The radio source 3*C*273 has been identified[1,2] with a star-like object of about thirteenth magnitude having a faint jet. However, the optical spectrum of the star contains a number of broad emission features which can be explained as hydrogen, magnesium and oxygen lines with a red-shift $\Delta\lambda/\lambda_0$ of 0·158 (refs. 2 and 3). Schmidt suggests that the stellar object is either a nearby ultra-dense star or, more probably, the abnormally luminous nuclear region of a galaxy at a distance of about 500 megaparsecs. The second possibility would make 3*C*273 the most luminous object known.

One method of deciding whether 3*C*273 is outside our Galaxy is to check whether its radio spectrum shows

absorption by the layer of neutral hydrogen in the galactic plane. Unfortunately 3*C*273 is at galactic latitude $b_{II} = 64°$, so that the opacity of the hydrogen layer is small. Over a large area around 3*C*273 the neutral hydrogen emission profile observed with a 14′ beam has a peak brightness temperature of 4° K and a half-width of 20 km/s (ref. 4). Assuming that the gas is uniformly distributed and has a spin temperature of 100° K, we could expect an opacity not greater than 4 per cent. With the 210-ft. reflector at Parkes the antenna temperature of 3*C*273 is 24° K, so that there would be an absorption dip of about 1° K if the source is extragalactic. A direct measurement of the absorption profile for this source with high accuracy presents considerable experimental difficulties.

Instead of measuring the whole absorption profile of 3*C*273, a shorter experiment has been performed to compare the opacity in front of this source and the source 3*C*270. The latter is only 4° away and has been identified[5] with the *E*3 galaxy *NGC*4261 in the Virgo cluster. Comparing the opacities makes it unnecessary to know the receiver characteristics extremely accurately. The 21-cm emission we observe with a beam-width of 14′ is uniform over the area around these sources, to that one would anticipate that the opacities would be similar.

A frequency-switching receiver was used to compare the radiation at the frequency of the peak of the line profile, f_1, with that at a frequency f_2, 3 Mc/s lower. If τ is the opacity of the gas in front of 3*C*273, the change in the receiver output between the source and the nearby sky can be written:

$$\Delta = G_1 \cdot e^{-\tau} \cdot T_1 - G_2 T_2$$

where G_1 and G_2 are the gains of the receiver at f_1 and f_2, $e^{-\tau}$, T_1 and T_2 are the antenna temperatures at f_1 and f_2. When $\tau \ll 1$ we can write:

$$\frac{\Delta}{G_1 T_1} \doteq \left(1 - \frac{G_2}{G_1} \cdot \frac{T_2}{T_1}\right) - \tau$$

Similarly for 3*C*270 we have:

$$\frac{\Delta'}{G_1 T_1'} \doteq \left(1 - \frac{G_2}{G_1} \cdot \frac{T_2'}{T_1'}\right) - \tau'$$

Hence:

$$\tau - \tau' \doteq \frac{\Delta'}{G_1 T_1'} - \frac{\Delta}{G_1 T_1} - \frac{G_2}{G_1}\left(\frac{T_2}{T_1} - \frac{T_2'}{T_1'}\right)$$

When $G_2 \approx G_1$, the last term will be about 0·1 per cent (taking spectral indices of 0·2 for 3*C*273 and 0·7 for 3*C*270 (ref. 5)), and this contribution can be ignored.

The measurements were made using a parametric receiver[6] with a noise temperature of 160° K, a bandwidth of 41 kc/s and a time-constant of 20 sec. The 210-ft. telescope was set on the source for periods of 5 min, followed by 5 min on a comparison region. Four comparison regions were used, 15′ away from the source in right ascension and declination. The effective integration time was about 20 min. One series of measurements was made in March 1963, another in June with the receiver tuning modified. The results are shown in Table 1. The error quoted is the standard deviation of the measurements.

Table 1

Date	Quantity	3*C*273	3*C*270
March 17	Δ/G_1	−0·14° ± 0·09° K	+0·15° ± 0·09° K
	Δ/G_1T_1	−0·6% ± 0·4%	+1·2% ± 0·7%
	$\tau - \tau'$	+1·8% ± 1·1%	
June 9	Δ/G_1	−1·61° ± 0·12° K	−0·66° ± 0·04° K
	Δ/G_1T_1	−6·7% ± 0·5%	−5·7% ± 0·4%
	$\tau - \tau'$	+1·0% ± 0·9%	

It will be seen that the opacity of the gas in front of 3*C*273 is not less than that in front of 3*C*270. Unless we invoke the unlikely possibility that there is a minute hole (diam. < 14′) through the galactic hydrogen in the direction of 3*C*270, this result supports Schmidt's suggestion that 3*C*273 is extragalactic.

We thank Mr. J. G. Bolton for suggesting the experiment and Mr. M. B. Mackey for assistance with the observations.

Radio Emission from Flare Star *V*371 Orionis

During the past three years the Division of Radiophysics, Commonwealth Scientific and Industrial Research Organization, Sydney, Australia, has made a systematic attempt to detect radio emission from a number of the so-called flare stars situated in the Sun's vicinity. Slee, Patston and Higgins[1] have described the earlier work and results. Lovell, Whipple and Solomon[2] have also recently published the results of a similar flare-star survey conducted at Jodrell Bank. Taken together, these two surveys have established with a reasonable degree of certainty that at least some of the flares on the six red dwarfs examined were accompanied by detectable radio emission.

The present communication describes the reception of a particularly intense burst of radio emission from the *dM*3*e* star *V*371 Orionis (Wachmann's star) at the time of an optical flare on November 30, 1962. This occurrence establishes beyond doubt, we believe, that flare stars are powerful radio emitters.

The optical observations were conducted jointly by a Baker–Nunn camera installed at Woomera, South Australia, and by two 10-in. telescopes operated by Australian amateur astronomers. Radio observations were made at frequencies of 1,410 Mc/s and 410 Mc/s with the 210-ft. reflector at Parkes, New South Wales, and at 19·7 Mc/s with the north–south arm of the low-frequency cross situated near Sydney. Each of the higher frequencies made use of a Dicke system in which the feed dipole was switched against a reference load and the receiver gain adjusted to produce a noticeable noise fluctuation-level on the recorder chart with a smoothing time constant of 2 sec. In the 19·7-Mc/s observations, the two halves of the north–south arm of the cross were connected to different total power receivers. One radio beam was directed at the flare star and the other about 3° away in order to identify terrestrial interference.

On November 30, 1962, between 14h40m and 14h54m U.T. the 210-ft. reflector received a burst of radio noise at a frequency of 410 Mc/s. Aural monitoring at the time showed that the deflexion was not caused by any recognizable form of interference. A tracing of the 410-Mc/s recording is given in Fig. 1, which shows a smooth rise in aerial temperature with a peak value of 8·2° K at 14h48m. The descending portion of the burst is characterized by a number of temporary decreases in aerial temperature lasting from 6 sec to about 20 sec.

Shortly before the commencement of the 410-Mc/s burst, two independent teams of amateur astronomers located at different sites near Sydney, observed the flar

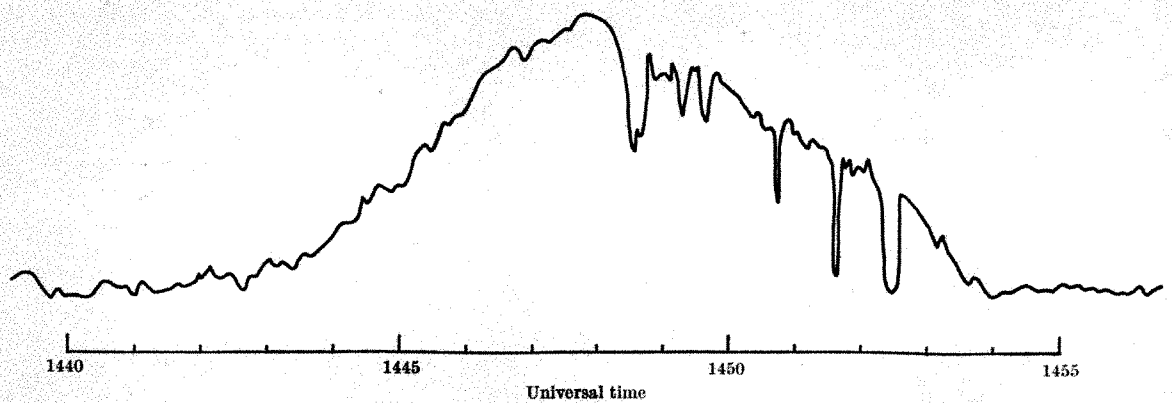

Fig. 1. Tracing of the 410-Mc/s record of November 30, 1962, during an optical flare on *V*371 Orionis

star to increase rapidly in brightness. The more detailed of the visual light curves is presented in Fig. 2*a* and shows a reasonably smooth variation in brightness with peak amplitude of about 0·6 magnitude.

At about the same time, the Baker–Nunn camera, using fast panchromatic film exposed for 8·8 sec in a 2-min cycle, recorded a definite onset of activity. This activity appears to have taken the form of a series of 'bursts' of energy, superimposed on a generally elevated level of brightness. However, it is possible that the increasing haze and cloud conditions (which caused termination of photography at 1507*Z*) and slippage of the film in transport through the camera (causing the photographed clock images to affect the star field) drastically affected the measured brightness of the star on some of these frames. The highest peak appears to have been about 1·0 magnitude above the quiescent brightness-level. Fig. 2*a* gives the results of the plate measurements, based on a modified Argelander estimation system.

The visual and photographic light curves show no detailed correspondence; this may be due in part to the difficulties described here. However, it is also possible that, superimposed on a smooth increase in the continuum in visual light, there were several flashes of blue or ultraviolet light. Alternatively, the flashes of light were in the visual region but of too short a duration to have been noticed by the observers, who were averaging the star's brightness over intervals of three or four minutes.

For the sake of completeness, the smoothed profile of the 410-Mc/s radio burst is shown in Fig. 2*b*. An investigation of the 1,410-Mc/s and 19·7-Mc/s radio records for the same night showed the existence of deflexions that were probably caused by the flare. On 1,410 Mc/s, a group of weak deflexions with peak excess aerial temperature of 0·52° K occurred between 14^h38^m and 14^h41^m U.T. The significance of these deflexions can be judged from the peak amplitude of the noise fluctuations of 0·13° K for the 10 min preceding and following the suspected flare-star radiation. Unfortunately, the 19·7-Mc/s record was marred by interference from a distant electrical storm. However, between 14^h32^m and 14^h48^m U.T. significant increases occurred in the base-level of the receiver connected to the radio beam directed at the flare star. No such radiation was received in the radio beam directed 3° away from the star, and no station interference could be heard in the loudspeaker. The intervals over which the probable flare radiation was recorded at 1,410 Mc/s and 19·7 Mc/s are shown in Fig. 2*b*.

The characteristic common to the radio bursts at all radio frequencies is their occurrence at, or close to, art of the optical flare; in this respect, they are to flare-induced solar-radio outbursts. From spectral data available, there appears to be no tendency for the high-frequency event to e lower-frequency burst as has been demonstra- e II solar outbursts. However, it is well known that the radiations emitted during a solar flare may have a very complex structure in the frequency-time plane, so that observations at widely spaced frequencies cannot be used to deduce the true form of the dynamic spectrum.

Table 1. Energies involved in Flare

Radio frequency or optical wave-length	Peak flux		Integrated flux	
	Density at Earth ($W\,m^{-2}(c/s)^{-1}$)	Radiated by star ($W\,(c/s)^{-1}$)	Density at Earth (joules $m^{-2}\,(c/s)^{-1}$)	Radiated by star (joules $(c/s)^{-1}$)
19·7 Mc/s	$2·3 \times 10^{-22}$	$1·6 \times 10^{14}$	$7·8 \times 10^{-20}$	$5·5 \times 10^{16}$
410 Mc/s	$1·2 \times 10^{-25}$	$8·5 \times 10^{10}$	$4·2 \times 10^{-23}$	$2·9 \times 10^{13}$
1,410 Mc/s	$8·6 \times 10^{-27}$	$6·0 \times 10^{9}$	$5·4 \times 10^{-25}$	$3·7 \times 10^{11}$
5,400 Å (visual)	$6·2 \times 10^{-28}$	$4·4 \times 10^{8}$	$1·6 \times 10^{-24}$	$1·1 \times 10^{12}$

The energies involved in the radio bursts are set out in Table 1, which also includes some estimates of the optical flare energies. Radio energy liberated at the star has been calculated from a recent parallax measurement by Van De Kamp[3] on the assumption that the source radiated uniformly into π steradians. The energy at optical frequencies was estimated from the increase in black-body radiation required to account for the brightness changes recorded by the visual observers. For these calculations, *V*371 Orionis was regarded as a typical *dM*3 star with $Te = 3{,}400°$ K and $\frac{R}{R_\odot} = 0·37$.

We have also estimated the total radio energy liberated during the flare by assuming (according to the data of Table 1) that the integrated flux varied as frequency $^{-2·5}$ over the complete radio spectrum and obtained a value of about 10^{24} joules. The corresponding optical energy radiated per 1000 Å was about 10^{26} joules.

It is interesting to compare these values with the corresponding radio and optical energies released during an intense solar flare. One of the most important solar-radio events was that of February 21/22, 1950, which[4] yielded about 10^{18} joules over the frequency-range 100–10,000 Mc/s, a value which is below the radio energy in the *V*371 Orionis event by a factor of 10^6. The continuum radiation in the optical region cannot be detected during the majority of importance 3 and 3+ solar flares and is estimated[5] to be < 1 per cent of the photospheric continuum emission per unit area. Hence over the area of a large flare that radiates at this rate for 1,000 sec, the optical energy emitted per 1000 Å is $< 10^{23}$ joules. Thus we see that the optical energy liberated by a $0·6^m$ flare on *V*371 Orionis exceeds that of an important solar flare by at least 1,000, and, unlike its solar counterpart, is not a trivial item in the energy balance of the whole star.

The form of the radio spectrum shows conclusively that the intense emission during a flare is due to a non-thermal mechanism. The total radio energy involved is only about

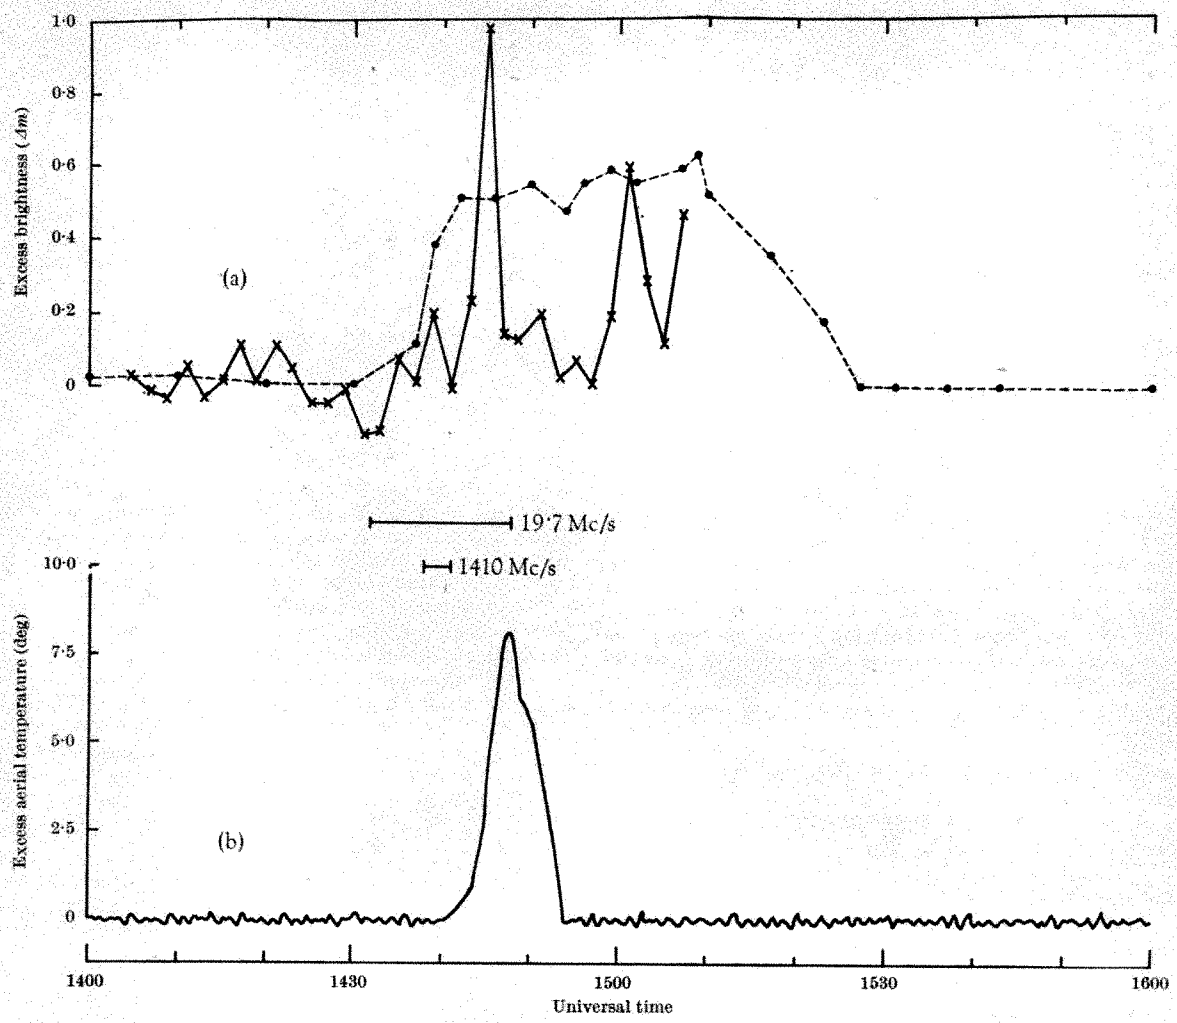

Fig. 2. (*a*) Light curves of the flare on *V*371 Orionis on November 30, 1962. Points marked ● refer to visual observations made by amateurs at Belfield Observatory, Sydney. Points marked × are measurements from the Baker–Nunn camera at Woomera, South Australia; (*b*) Smoothed profile of the radio burst at 410 Mc/s. The durations of probable burst activity at 19·7 Mc/s and 1,410 Mc/s are also indicated

1 per cent of the total optical energy liberated, but is probably a larger proportion of the total energy than the corresponding quantity for a solar flare. It is apparent that we are here dealing with a more efficient method of converting kinetic energy to radio energy. Synchrotron radiation by relativistic electrons gyrating about magnetic field lines is known to yield high ratios of radio to optical energy in some of the discrete radio sources. If such a mechanism is operating here, it may be possible to detect linear polarization in the flare radiation at the higher frequencies.

Finally, it is of interest to compare the radio flux from *V*371 Orionis with that received from the 6 flare stars investigated in the surveys[1,2]. In the Sydney survey conducted mainly at 85·5 Mc/s, 11 visual flares yielded an upper limiting value for the average peak flux density of 95 flux units per magnitude of peak brightness variation (1 flux unit $= 10^{-26}$ Wm^{-2} $(c/s)^{-1}$). The corresponding value obtained from 10 of the brighter flares in the Jodrell Bank survey at 240 Mc/s was 4·2 flux units per magnitude change. If we convert the 85·5 Mc/s value to 240 Mc/s by using a frequency $^{-2.5}$ spectrum found to apply to the *V*371 radio burst, we obtain a value of 7 flux units per magnitude (upper limit), which is in reasonable agreement with the Jodrell Bank result. Using the same spectral law on the *V*371 Orionis outburst, we find that the peak flux density observed at 240 Mc/s would be 45 flux units per magnitude of brightness change. This is an order of magnitude higher than the average value observed during the Sydney and Jodrell Bank flare-star surveys and may be additional evidence for an efficient process of energy conversion in this particular star.

We thank the Australian amateur astronomers, especially Messrs. L. Lockwood, R. Brownett, J. Flavin and K. Lay, who observed the flare visually. The 19·7-Mc/s radio observation was made by Mr. C. S. Higgins, and the Baker–Nunn exposures were made possible by the co-operation of the Australian Department of Supply.

PHYSICS

Re-entrant Motion in Special Relativity

A recent communication[1] describes three methods of measuring the peripheral velocity of a disk rotating with fixed angular velocity. The purpose here will be to examine methods 'B' and 'C' in a little detail.

Let us suppose that a number (n) of closely spaced fiducial marks are made in the laboratory system all around the periphery of a rotating disk; these are numbered consecutively from 1 to n in the direction of disk rotation. At the location of each mark is a clock. These clocks are synchronized by some convention; the conclusions drawn here are convention-independent, but we may suppose that the usual (Einstein) convention is used. By t_0 will be meant a time at which a single fiducial mark on the disk coincides with mark n in the laboratory, as recorded by the clock located at mark n; by t_i, $i=1, \ldots, n$ will be meant the time first following the coincidence at time t_0 at which the mark on the disk coincides with mark i, as recorded by the clock located at mark i.

Method B may presumably be applied in connexion with any two adjacent marks to find the disk-edge speed v_B. Furthermore, the value obtained for v_B should not depend on which pair of marks is used. Hence it follows that the distance (measured in the laboratory) between adjacent marks i–1 and i (where mark n is also called mark 0) is given by:

$$d_i = v_B(t_i - t_{i-1}),\ i=1, \ldots, n$$

If this is summed from $i=1$ to n, there follows:

$$\Sigma_i d_i = v_B(t_n - t_0)$$

On the other hand, the speed v_C obtained by method C is related to the circumference of the disk $2\pi r$ by:

$$2\pi r = v_C(t_n - t_0)$$

But $2\pi r$ also equals $\Sigma_i d_i$, according to the definition of circumference. Hence v_C equals v_B, contrary to the conclusion reached by Dr. Phipps.

It should now be apparent that Dr. Phipps's analysis of circular motion, based on the assumption that $v_C \neq v_B$, cannot easily be supported by analysis consistent with elementary mathematics; moreover, that a non-equality of v_B and v_C would be most disturbing, in view of the great similarity in the operational definition of the two velocities. Few doubts should remain, for there is nothing in this communication to disprove the applicability of special relativity (with all its traditional idealizations) to problems of re-entrant motion.

A Fundamental Extension of Einstein's Diffusion–Mobility Relationship

Many readers will no doubt have observed that the concepts of particle-diffusion force and gained energy, which were put forward recently[1] under the above title in these columns, are long familiar in the field of irreversible thermodynamics.

The Einstein relation between diffusion coefficient and mobility is theoretically valid in the limiting case of an infinitely low concentration of diffusing solute. In this limit the 'gained energy' is exactly the chemical-potential difference per particle. The particle-diffusion force is the gradient of chemical potential which at constant temperature is proportional to the generalized thermodynamic force of Onsager[2] conjugate to diffusive flux.

These basic concepts, as is suggested in ref. 1, are indeed essential in the investigation of transport phenomena and have, in fact, a much wider range of validity than has the Einstein relationship. Generalized thermodynamic forces are defined for concentrated and multicomponent solutions, and not only for diffusive transport, but for any irreversible fluxes of energy or particles. Such fluxes J_i are related in a conjugate manner to forces X_i by a calculation of the rate of production of entropy σ in their presence:

$$\sigma = \sum_i J_i X_i$$

For diffusive flux:

$$X_i = -\frac{1}{T}(\text{grad}\ \mu_i)_T$$

where μ_i is the chemical potential of species i.

The thermodynamics of irreversible processes, as a phenomenological theory, has been brought to a satisfactory state of formality over the past thirty years, and there are several excellent texts[3] available. It seems, however, to occupy a 'no-man's land' between chemistry and physics and is not as widely disseminated in schools of either chemistry or physics as it might be. It would provide useful material for a first-year graduate course, and, as a statistical-mechanical theory, is a new and rapidly expanding field for research.

Suppression of Dust

While examing the beneficiation of fine coal from the Bulli seam, New South Wales, by froth flotation, the hydrophobic characteristics of the coal were observed. Air-borne dust from this seam had an average composition of fixed carbon 60 per cent, volatiles 26 per cent, ash-forming constituents 12·5 per cent and moisture 1·5 per cent. This dust contained a high proportion of vitrain.

Methods of dust suppression which had been examined included water infusion into both pillar and solid coal, water sprays and wetting agents. These methods had proved to be unsatisfactory, and in addition it was considered that their practice would interfere with subsequent beneficiation. It was decided that methods of suppression which made use of the coal characteristics and which may also be useful in subsequent beneficiation work should be examined.

Since the coal was hydrophobic, it appeared that three methods could be used to induce suppression.

Laboratory investigations were carried out using a dust chamber in which dust counts could be made at selected intervals of time to compare the effectiveness of suppression in treated coal. The first method utilized reagents commonly used as depressants in coal flotation to induce hydrophilic surface properties on the coal particles, thereby inducing wettability and subsequent suppression by sprays. Reagents used included potassium permanganate, but results were generally unsuccessful as this coal was difficult to depress. Results using other oxidizing reagents

showed no improvement when compared with water, and in some instances were inferior.

In the second series of tests, various coal flotation reagents (collectors) were used to induce agglomeration by adhesion similar to that achieved in froth flotation. Some success was achieved. With oils and alcohol frothers, particle adhesion and suppression were obtained. Work on the process was discontinued because of the problems which would arise if these materials were to be used in the mine.

For the third method, particle adhesion or agglomeration using flocculating reagents was attempted. Previous work on coal flotation had shown the possibility of floating coal, oxidized coal and ash-forming constituents using amine reagents, which also induced excellent flocculation.

Amine reagents gave satisfactory results and afterwards tests were made using starch, which is commonly used as a flocculant in coal preparation.

Starch is a non-toxic reagent and is therefore suitable for use in a mine. Further, its admittance to the washery circuit water would not influence washery performance. It is already in common use in washeries as a flocculating reagent.

Results obtained when starch was added to the water used for suppression in the dust chamber tests were satisfactory. Further, coal which was treated with starch, when dried and re-wetted by a water spray, retained to a marked degree its reduced dustiness.

It is probable that any non-toxic polyelectrolytes or polyacrylamides commonly used as flocculating reagents would give satisfactory results as dust suppressing reagents.

Adhesion induced by the use of flocculating reagents forms a practical method of dust suppression, especially in handling dust particles which are hydrophobic.

Size and Growth of Cavitation Bubble Nuclei

Some years ago, one of us (K. S. I.), working in the laboratory of the late Prof. E. G. Richardson (King's College, Newcastle upon Tyne), made use of sound reverberation and optical scattering methods[1] in an attempt to detect the presence and determine the size-distribution of nuclei responsible for the low tensile strength of liquids. During the course of the experiments it became evident that the nuclei existed in two forms in water—as stable air bubbles and as solid suspensions. The bubble nuclei, apart from possessing other unique features, were characterized by measurements of a consistent and reproducible nature when water containing them was subjected to ultrasonic and hydrostatic pressures. The measurements associated with the solid nuclei were erratic and showed considerable scatter.

The bubble nuclei pulsate in an acoustic field and expand rapidly into visible size when the intensity of the field reaches the cavitation threshold. In water saturated with air, a fully grown bubble remains stable while in under-saturated water it quickly reduces in size and disappears when the acoustic field is cut off. Theoretically cavitation, or the growth of a bubble nucleus to visible size, should occur when the ambient hydrostatic pressure falls below the pressure of the air inside the bubble. This can happen during the rarefaction part of the acoustic cycle when the hydrostatic pressure temporarily becomes negative. Since the internal pressure is a function of the size of the bubble and the surface forces acting on it, the cavitation threshold will depend on these factors. The nature of this dependence can be experimentally determined in the following manner.

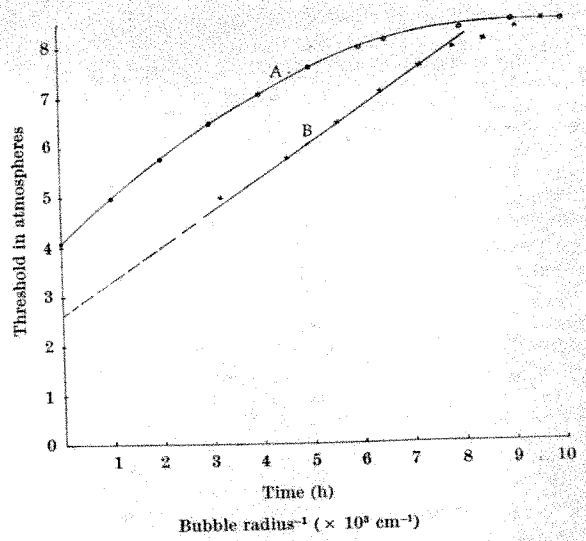

Fig. 1

A convergent beam of ultrasonics is focused on a small region of freshly drawn tap-water kept in a vessel. Initially the water may contain visible bubbles which soon rise to the surface and disappear, leaving a clear liquid without a trace of a rising bubble even when examined under the microscope. If the intensity of the sound is now

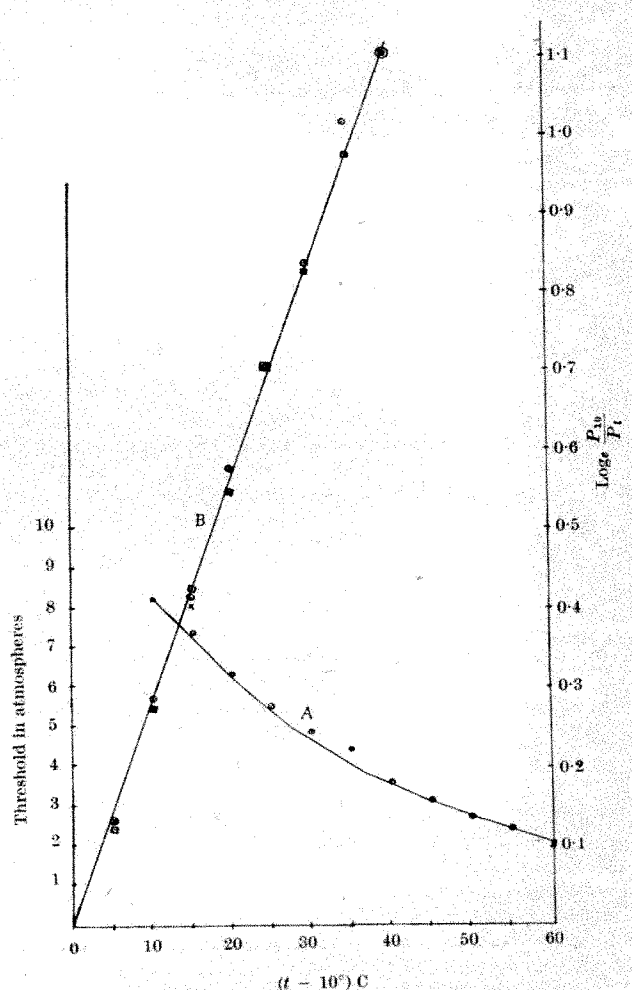

Fig. 2. ×, Conolloy and Fox; ○, fundamental; □, third harmonic

gradually increased, visible bubbles appear at the focus at an acoustic pressure corresponding to the cavitation threshold. If the water remains undisturbed, this threshold pressure rises steadily and becomes constant after several hours as shown in Fig. 1 (*A*). The steady rise in the threshold can be explained as due to the difference in the size of the bubble nuclei, as they ascend through the water, past the focus with a rate of rise given by Stokes's formula $r^2=\frac{d}{2\times 10^4 t}$, the smaller nuclei taking longer time to reach the focus from the base of the vessel. Knowing d, the distance between the base and the focus the radius of the bubble is easily calculated from the time of rise. In Fig. 1 (*B*) the reciprocal of the bubble radius calculated in this manner has been plotted against the corresponding threshold pressure P. The relation which is linear is given by the general expression:

$$P=a+b/r \qquad (1)$$

The constants a and b are affected by the surface contaminations of the bubble and may vary slightly for different samples of water. a is of the order of one atmospheric pressure, and b has a value of about 500 dynes/cm. The plots corresponding to the smaller bubble nuclei shown at the top of the graphs deviate from the straight line relation indicating the failure of Stokes's law when applied to bubbles of 1μ or less. Nuclei of this size remain trapped in water due to the thermal agitation of the molecules. The size of the nuclei reported by other workers[2] are in good agreement with these values.

The cavitation threshold of tap water shows considerable variation in temperature. We have measured the change in the temperature-range 10°–60° C, with a focused beam of ultrasonics generated by a polarized bowl of barium titanate. The behaviour is shown in Fig. 2 (*A*). Plotted on logarithmic scale the threshold varies linearly with temperature. Fig. 2 (*B*) is a plot of $\log_e P_{10}/P_t$ against the temperature interval $(t-10)$ where P_{10} is the threshold pressure at 10° C. The measurements were made with two excitations of the bowl—the frequencies of the fundamental and the third harmonic. The data obtained by Fox[3] at a frequency 1 Mc/s are also shown plotted. All these points lie on a single straight line leading to the expression:

$$P_t=P_{10}\,e^{-\alpha(t-10)} \qquad (2)$$

As the size of the bubble nucleus determines the cavitation threshold the exponential fall of the pressure is indicative of the fact that the growth-rate of the nucleus is exponential when the temperature is raised. Combining expressions (1) and (2) the change in the radius of the nucleus with temperature may be shown to be $r_t=r_{10}e^{\beta(t-10)}$ where $\beta=\left(\frac{ar_t}{b}+1\right)\alpha$. Assuming the value $1\cdot5\times10^6$ dynes/cm^2 for a and 5×10^2 dynes/cm for b, and the measured value 0·02/deg. C of α, the calculated rate of size increase β is 0·026/deg. C when the nucleus is one micron in radius and 0·08/deg. C when the same nucleus grows to 10 times its former size, showing that the growth rate increases with size.

GEOLOGY

Age Measurements of Antarctic Rocks (Queen Maud Land)

This communication is a report of the age measurem project carried out on rocks from the Sör-Rondane Mo tains (Queen Maud Land, 23° E. to 28° E.). The ro were sampled by Picciotto[1,2] during the 1958 Belg Antarctic Expedition led by Gaston de Gerlache[1]. first set of results has already been published[3]. T biotite strontium/rubidium ages of various eruptive a metamorphic rocks ranged from 460 to 500 million yea

Radiogenic strontium-87 is known to migrate out biotite minerals[4,5]. In the available samples, miner other than biotite have been selected together w whole rocks of sufficient high rubidium/strontium rat Isotopic measurements on zircons were also carried o

The analytical methods used are close to those describ by Aldrich *et al.*[6] and Tilton *et al.*[7]. The geological a petrographic descriptions of the Sör-Rondane Mountai have been published by Picciotto *et al.*[8] and Michot[9,10].

The new results, given in Table 1, confirm the existen of a magmatic and metamorphic activity, roughly 5 million years old (between 460 and 600 m.y.). No great ages have been found in this region.

† B, Biotite; M, muscovite; F, feldspar; WR, whole rock; Z, zircon.
‡ $\lambda_{^{87}Rb}=1\cdot39\times10^{-11}$ yr.$^{-1}$, rubidium-87 = 0·283 g/g rubidium.
§ Common strontium $^{87}Sr/^{86}Sr$ = 0·709 (measured on calcic feldspar fro Bautaen granite).
¶ $\lambda_{^{238}U}=1\cdot54\times10^{-10}$ yr.$^{-1}$, $\lambda_{^{235}U}=9\cdot72\times10^{-10}$ yr.$^{-1}$.

The small, but systematic, discordance between th younger biotite ages and the older whole rock and zirco ages seems to be significant. It follows a pattern alread described in the literature[11].

In the present case, our tentative interpretation is a follows: the emplacement of the intrusive-type granite (Nordtoppen, Romnoesfjellet and Gunnestadbreen) an the differentiation of the fine-grained 'anatectic' granite occurred between 500 and 600 million years ago. A distinct phase of the geological evolution of this regio might have happened around 480 m.y. ago; it coul correspond to an uplift of the rocks into a superficia zone where radiogenic strontium-87 diffusion has stopped according to the views of Hurley *et al.*[5]. An alternat interpretation would be to assume, at this time, a retro morphose mesozonal episode. Evidence of such a retro morphose has been observed in thin sections[9,10].

We thank Drs. J. Michot and E. Picciotto for stimulating discussions.

CHEMISTRY

Extensive Reduction of Coal by a New Electrochemical Method

In recent years electrolytic methods have been used in the reduction and structural elucidation of coal[1-2]. The usefulness of these methods is limited by the fact that the benzene ring (that is, the isolated benzene ring as in benzene or tetralin), which may represent a large portion of the coal structure, has not previously been reduced electrolytically. Work here has shown that reduction of benzene can be achieved by electrolysis in ethylenediamine saturated with lithium chloride[3]. The same method has now been successfully applied to the reduction of a high-rank coal and has resulted in the addition of 44 hydrogens per 100 carbon atoms. The best electrochemical reduction achieved[2] prior to this was carried out in dimethylformamide and amounted to the addition of 14 hydrogens.

Six grams of the coal (Pocahontas vitrain ground to pass 325 mesh) suspended in 100 ml. of ethylenediamine containing 1·4 g of lithium chloride was electrolysed at 33° between carbon electrodes at 0·5 amp and 115 V. Apparatus and technique of electrolysis[3] and recovery of the reduced coal[4] were the same as described previously. Current efficiency at the beginning of the electrolysis was 46 per cent and dropped to 10 per cent after 15 h. The electrolysis was continued for an additional 15 h, during which time the current efficiency remained practically constant. The reduced coal was recovered from the solution in 95 per cent yield, analysed and subjected to a second and third electrolytic reduction; it was tan-grey in colour. Analyses of the original and reduced samples are shown in Table 1.

Table 1. Electrochemical Reduction of Pocahontas No. 3 Vitrain

	Grams	C	H	N	S	Ash	H atoms added* per 100 C atoms in starting material
Original vitrain	—	87·66	4·22	1·06	0·65	2·45	—
	—	87·97	4·42	1·08	0·73	2·39	—
First reduction	6·10	83·05	6·43	3·39	0·63	2·55	24·3
	—	84·19	6·18	3·44	0·95	2·52	—
Second reduction	5·80	80·72	6·95	4·47	0·36	2·47	32·4
	—	80·80	7·12	4·32	0·38	2·39	—
Third reduction	3·16	80·73	7·73	4·15	0·39	2·76	43·7
	—	80·48	7·76	4·24	0·25	3·03	—

* Method of calculation as described in ref. 4.

The ratio of lithium chloride used to total hydrogen taken up by the coal was about 1 : 2. This ratio is much more favourable than that obtained in the chemical reduction of the same coal[4] where the ratio of lithium metal to hydrogen added was 1 : 0·1. An interesting resul its the fact that the solubility of the electrolytically reduced coal in pyridine at room temperature (74 per cent) is higher than that of the chemically reduced coal. In the latter case, 45 hydrogens were added but the solubility was only 63 per cent. It is conceivable that chemical reduction at elevated temperature, in contrast to electrolytic reduction at room temperature, is accompanied by polymerization resulting in a decrease in solubility. The advantage of ethylenediamine over dimethylformamide[2] is probably connected with the fact that ethylenediamine can solvate lithium. Experiments[3] indicate that lithium acts as an electron transfer agent in the reduction of benzene in the ethylenediamine–lithium chloride system.

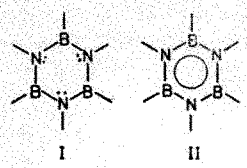
Interaction of Methyl-substituted Borazines with Various Acceptor Molecules



It has been suggested that borazines might be expected to form molecular complexes with electron-pair acceptors[1], and interactions between hexamethylborazine and tetracyanoethylene[2] or iodine[3] have been reported. In further support of this suggestion we wish to report the initial results of a spectrophotometric investigation of the interaction between methyl-substituted borazines and some acceptor molecules. Solutions of B-trimethyl-, B-trimethyl-*N*-methyl-, B-trimethyl-*N*-dimethyl-, and hexamethyl-borazine in carbon tetrachloride and in *n*-heptane exhibit featureless absorption spectra in the range 600–200 mμ, but the spectra of mixtures containing these borazines and typical acceptor molecules in the same solvents exhibit bands which are not characteristic of the acceptors. (See Table 1 for some representative data.)

Table 1. Positions (mμ) of New Absorption Bands exhibited by Mixtures of Some Methyl-substituted Borazines and Various Donors*

	$(Me)_3B_3N_3H_3$	$(Me)_3B_3N_3H_2Me$	$(Me)_3B_3N_3H(Me)_2$	$(Me)_3B_3N_3(Me)_3$
Iodine	290	289, 390	294, 390	291, 390
Picric acid	250†	260†, 433	258†, 455	258†, 455
p-Benzoquinone	none	335	335	335
Chloranil	none	345	350	345
Tetracyanoethylene	—	321	320	320

* 10 : 1 mole ratio of borazine to acceptor, at a concentration of 10^{-3} M.
† Shoulder.

The new bands appear in the spectral region in which charge-transfer bands for aromatic systems occur and can be attributed to molecular complexes formed between the borazine and the acceptors. It is noteworthy that complex formation involving B-trimethylborazine produces the smallest effect on the spectra of the free acceptor molecules, and that mixtures of B-trimethyl-*N*-methyl-, B-trimethyl-*N*-dimethyl-, or hexamethyl-borazine with the same acceptors exhibit substantially equivalent spectra. The spectra of iodine, sulphur dioxide, maleic anhydride, tetracyanoethylene, *p*-benzoquinone, picric acid, chloranil, and iodine monochloride are markedly affected by the addition of tetra-, penta-, or hexa-methylborazine; the last three named acceptors undergo a further slow reaction, and orange-coloured precipitates separate from mixtures containing picric acid on standing.

I II

The formation of molecular complexes containing the borazine nucleus is not necessarily indicative of its 'aromatic nature'. Theoretically, borazines could form complexes with Lewis acids if the π electrons were either localized on the nitrogen atom (I) or if they were partially delocalized (II) as in benzene. In the former case borazine would be formulated as a cyclic triamine and it would be expected to act as a Lewis base. It is well established that amines form molecular complexes with some of the same donors which interact with aromatic systems, for example, sulphur dioxide and iodine. In addition, several strong donors, for example, hydrogen chloride, bromine, and chlorine, are known to add to adjacent boron and nitrogen atoms in the borazine nucleus to form the corresponding analogues of *cyclo*hexane. The solids which separate from mixtures of picric acid and the borazines may have been formed by a similar addition.

We thank the Robert A. Welch Foundation for supporting this investigation.

Dissolution of Glass at Elevated Temperatures

The finite solubility of glass containing vessels has long been the concern of chemists interested in the properties of solutions and hence in preparing solutions of accurately controlled composition. By the use of certain types of glass or of silica this problem can, to a large extent, be eliminated at temperatures near ambient. However, recently, certain experimental results have been obtained which have brought to our notice the high solubility of a hard borosilicate glass at elevated temperatures.

An attempt to use glass feed tubes in a boiler operating at 200° C was unsuccessful owing to the high rate of solution of the glass. A stout tube of wall thickness of more than 1 mm was reduced to paper thinness after exposure to oxygenated sea water at 200° C for 16 weeks. Even when exposed for some time to salt solutions boiling at atmospheric pressure, glass beakers have been found to undergo marked etching rendering them partially opaque.

A more striking example of the errors which can be introduced by neglecting glass solubility has recently been obtained during an investigation of the dissolution of zinc in millimolar sodium chloride at elevated temperatures in glass-lined autoclaves. The product obtained was generally found by X-ray analysis to consist of zinc oxide or an unknown compound giving a diffraction pattern identical with one of a series found by Gilbert[1] and designated by the letter *E* (Fig. 1). This compound was found to be insoluble in acids and further examination of the product and comparison of its diffraction pattern with those of the *A.S.T.M. Index* proved it to be a well-crystallized specimen of zinc pyrosilicate hydrate ($Zn_4(OH)_2Si_2O_7.H_2O$, hemimorphite) (Fig. 1). Samples of this material could be prepared at 80° C, 140° C and 200° C by exposure of the zinc to the above oxygenated solution for several hours. In Gilbert's experiments this compound was formed at atmospheric pressure after exposure of zinc

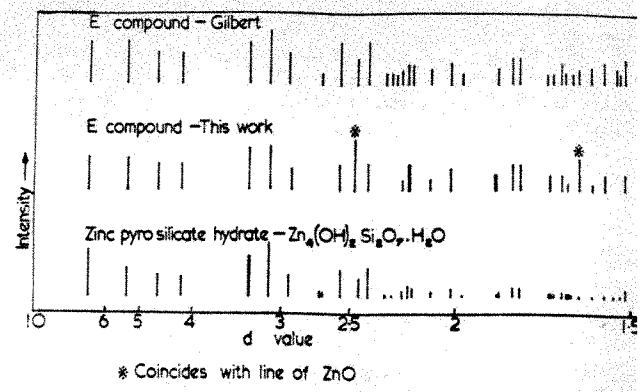

Fig. 1

or zinc hydroxide to distilled water at 85° C for periods of 35 days and upwards. It is quite clearly associated with dissolution of silica in some form from the glass container and interaction with the zinc corrosion product to give the silicate. In a separate experiment the dissolution rate of a borosilicate glass liner was found by loss of weight to be 0·22 mg/dm²/day at 140° C. This agreed closely with the amount of silica found by analysis in the millimolar chloride solution used.

The fact that the dissolution of glass is appreciable in distilled water and dilute salt solutions at temperatures as low as 80° C is noteworthy and should be borne in mind in chemical tests and, in particular, in dissolution tests on metals since silicates are well-known corrosion inhibitors.

Rates of Acid Hydrolysis of 2-substituted Methyl Glucopyranosides

The hydrolysis of methyl glycosides probably proceeds through the formation of an oxonium salt as intermediate[1–3]. The steps involved in the reaction of water with a methyl glycoside may thus be represented:

where k_3 represents the rate constant for what is generally believed to be the rate-controlling step.

Shafizadeh[4] has stressed how the inductive effect of a hydroxyl group at C-2 (*X*) may be used to explain the difference in the rates of acid hydrolysis of the methyl glycopyranosides of D-glucose and of 2-deoxy-D-glucose. He has further pointed out the similarity in the effect of a β-hydroxyl group on the stability in acid between these methyl glycopyranosides and the corresponding diethyl acetals.

I wish to indicate how the effect of a C-2 substituent on the rate of hydrolysis of a methyl glycopyranoside may be related in a quantitative way to the *pK* value of the corresponding substituted acetic acid.

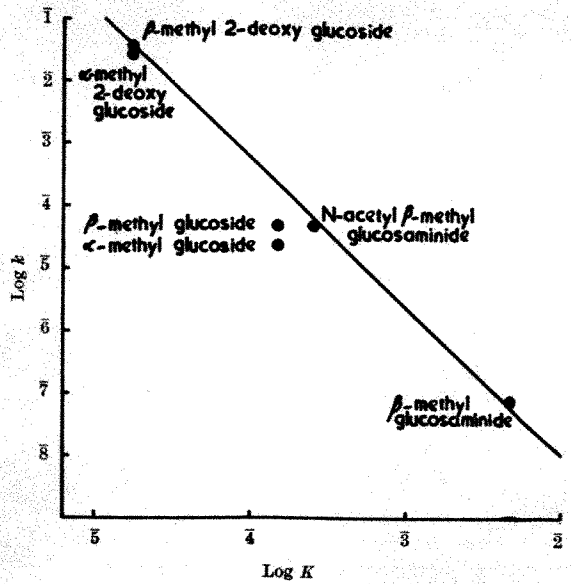

Fig. 1. Relationship between the rates of hydrolysis (k in sec^{-1} units) of various 2-substituted methyl glucopyranosides in N acid at 72·9° and the apparent dissociation constants (K) of the corresponding substituted acetic acid at 25°

If one considers the series of methyl glucopyranosides in which X, the substituent on C-2, is in turn H—, OH—, CH_3CONH— and NH_3^+—, then as X becomes more electron-attracting, the formation of the oxonium salt will be inhibited. The rate constants for hydrolysis (k) at 72·9° in presence of a molar concentration of hydrogen ions for such a series of compounds have been compared with the equilibrium constants (K) for the acid dissociation of the corresponding series of carboxylic acids. Some of the rate constants were obtained in hydrochloric acid and some in perchloric acid, those obtained in the latter tending to be a little larger than those obtained in hydrochloric acid of the same concentration[5], since the reactivity is related directly to the Hammett acidity function. However, the differences in rates of hydrolysis occasioned by the different acids are small relative to those due to inductive effects so that for present purposes they may be ignored. The values are shown in Table 1.

When log k is plotted against log K (Fig. 1), a linear relationship is obtained, indicating a relationship of the form:

$$\log k = \rho \log K + A \qquad (1)$$

the type of relationship envisaged by Hammett[9]. The value of ρ found is $-2{\cdot}34$ (cf. the value $-3{\cdot}65$ for the hydrolysis in acid of various ethyl acetals[10]). It seems reasonable to suppose that since the increased acidity of the carboxyl group of glycollic acid or glycine relative to that of acetic acid is due to the inductive effect of the hydroxyl or positively charged amino group respectively[11], so also is the lower reactivity of β-methyl glucoside or glucosaminide[8] relative to that of β-methyl 2-deoxyglucoside.

Table 1. Rates of Hydrolysis in Molar Acid Concentration at 72·9° for the Series of 2-(X-Substituted)-Methyl Glucopyranosides for Various X Substituents

Methyl glycoside of compound where X =	Anomer	Rate of hydrolysis 10^5 k (sec^{-1})	Corresponding acid	Acid dissociation constant (pK 25°)
—H	α	2·4 × 10^6 (*a*)	Acetic	4·76
	β	3·5 × 10^6 (*a*)		
—OH	α	2·5 × 10^5 (*b*)	Glycollic	3·83
	β	5·0 × 10^5 (*c*)		
—NHCOCH$_3$	β	4·6 × 10^5 (*d*)	Acetyl glycine	3·60
—NH$_3^+$	β	7·6 (*d*)	Glycine	2·35

(*a*) In perchloric acid, extrapolated from data in ref. 5; (*b*) in hydrochloric acid, ref. 6: corresponding value in N perchloric acid = 1·0 × 10^5, ref. 1; (*c*) in hydrochloric acid, ref. 7: corresponding value in N perchloric acid = 2·1 × 10^5, ref. 1; (*d*) in N hydrochloric acid, from data in ref. 8.

The reactivity in acid solution of methyl D-glucoside would be expected to be about 5·3 times less than that of methyl 3-deoxy-D-glucoside using our ρ value in equation (1) together with the pK values (at 25°) for glyceric acid (3·55) and lactic acid (3·86). This value agrees fairly closely with that which has been found for the α-anomers (7·4 times)[12].

For a given aliphatic aglycon it is probable, therefore, that the largest differences in the rates of hydrolysis of the resulting pyranoside are due to differences in the inductive effect of the substituent at C-2. Substituents at the remainder of the carbons have much less effect in altering the reactivity of the methyl glycosides of the pyranoses[4]. The operation of this inductive effect explains why, in naturally occurring compounds, the glycosidic bonds involving neutral sugars are cleaved by acid much more readily than those involving amino sugars.

I thank Prof. A. Neuberger for helpful discussions.

Enhanced Photoreactivity of Riboflavin in Aqueous Solution in the Presence of Macromolecules

The photoreduction of riboflavin in aqueous buffered solutions illuminated with visible light is considerably enhanced when colloidal substances such as micellar sodium decyl sulphate, the non-ionic surface-active agent polyoxyethylene 20 sorbitan mono-oleate, and the non-ionic polymer polyvinylpyrrolidone are present. Although a part of the catalysis produced by the non-ionic surfactant and the polyvinylpyrrolidone might be attributed to the

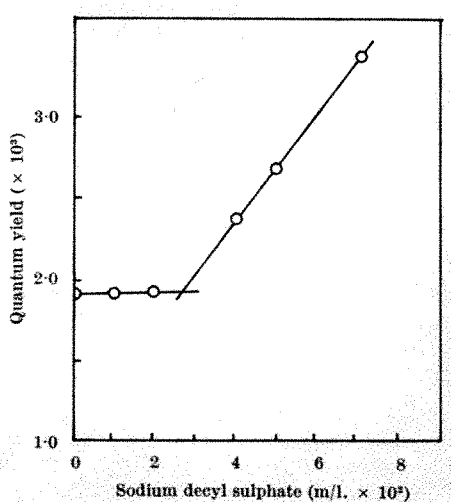

Fig. 1. Effect of sodium decyl sulphate on photoreduction of riboflavin by visible light in 0·05 M phosphate buffer, pH 6·8, 26° C

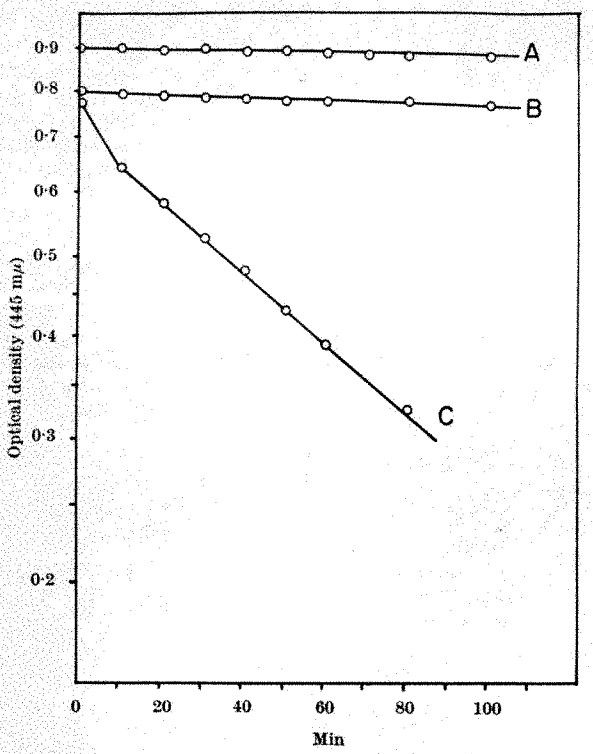

Fig. 2. Influence of micellar sodium decyl sulphate on rate of photo fading of acetyl riboflavin in 0·05 M phosphate buffer, *p*H 6·8, 26° C. Acetylriboflavin in: *A*, 0·07 M sodium decyl sulphate; *B*, 0·01 M ascorbic acid; *C*, 0·07 M sodium decyl sulphate plus 0·01 M ascorbic acid

presence of residual reducing groups, the effect of micellar sodium decyl sulphate appears to be wholly a result of its colloidal nature. Non-micellar sodium decyl sulphate has no effect on the photolysis of riboflavin as illustrated in Fig. 1.

Acetylation of the riboflavin side-chain hydroxyls produces a relatively light-stable compound, since normally the proton involved in the photoreduction originates from the ribityl side-chain[1]. As shown in Fig. 2, the light stability of acetylriboflavin is not influenced by micellar sodium decyl sulphate unless a reducing agent such as ascorbate is added to the system; the presence of the ascorbate without sodium decyl sulphate, however, has little influence on the light stability of acetylriboflavin.

The observed catalytic effects are attributed primarily to interaction of an excited riboflavin species, probably triplet, with the micellar surfactants and polymers[2]. The enhanced photoreactivity in such systems suggests certain similarities between these models and photochemical processes occurring in aggregated states in biological systems.

This investigation was supported by a grant, *RG*-9957, Division of General Medical Sciences, United States Public Health Service.

BIOCHEMISTRY

The Possible Biological Function of Pseudocholinesterase

Although the main function of acetylcholinestera (AChE) at the synapses of cholinergic nerves has bee fairly well established, the biological role of pseud cholinesterase (PsChE) has not[1–3,13]. It has been pr posed, however, that the latter enzyme is concerned wit relatively slow nerve conduction processes[3], and that th blood cholinesterases might be important in limitin responses to hydrolysable cholinergic agents[4].

Acetylcholine (ACh) is hydrolysed very quickly an butyrylcholine (BuCh) very slowly by AChE whil PsChE hydrolyses BuCh very rapidly, at about 2–3 time the rate of ACh[5]. Burgen and MacIntosh[6] suggested tha the natural substrate for PsChE might be somethin other than ACh. This substrate may be BuCh since i seems to be hydrolysed by PsChE more rapidly than an other substrate[7].

The capacity for ACh synthesis is widely distributed i animal tissue but is predominant in nervous structures and liver tissue (serum PsChE is also formed in the liver[8]) it requires the presence of adenosine triphosphate, co enzyme A (CoASH), acetate or citrate, choline and th enzymes acetyl kinase and choline acetylase[6,9].

In tissues, especially those of the liver, certain othe acyl-coenzyme A derivatives are equally capable of takin the place of acetyl-coenzyme A ($CH_3.CO \sim SCoA$) to giv the corresponding choline esters[9].

In mammals, fatty acid metabolism occurs mainly in th liver. Since the penultimate product of fatty acid degen eration and the primary product of lipogenesis in the fatt acid cycle[10] (Fig. 1, in thin lines) of fatty acids having eve numbers of carbon atoms is butyryl-coenzyme A, w

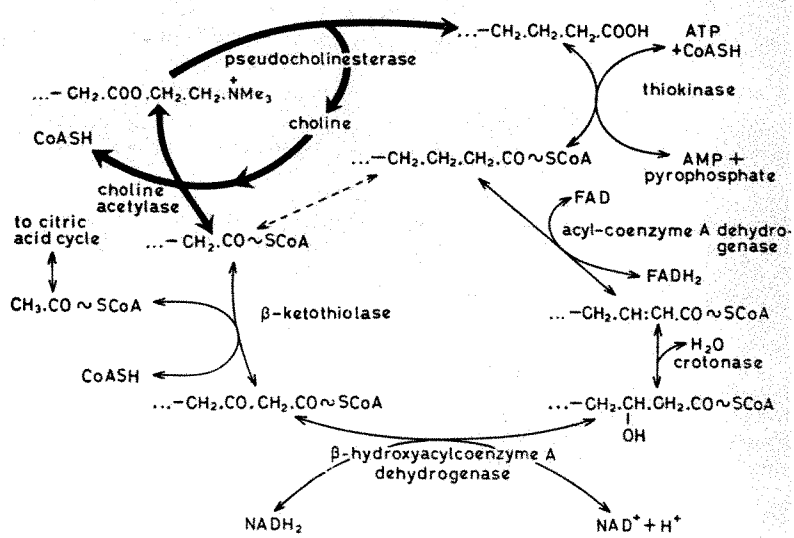

Fig. 1. Pathway of fatty acid metabolism in mammalian liver (—) including postulated synthesis and breakdown of toxic choline esters (—)

postulate that this, and to a lesser extent the acyl coenzyme A derivatives of certain other higher fatty acids, become involved in the choline ester synthetic pathway The products, particularly BuCh, have a powerful nico tinic action[11] and if not quickly destroyed would probably exert undesirable and toxic effects. We consider that the principal biological function of PsChE might, therefore be to hydrolyse this BuCh preferentially, almost at the site of its formation and allow the products of hydrolysis to return to their respective metabolic pathways (Fig. 1 in thick lines).

Some support for this hypothesis is provided by the seasonal variation observed in the PsChE titre of horse

serum, which reaches a maximum in late summer[12] thereafter declining, to parallel closely the seasonal variation in fat metabolism.

γ-Aminobutyrylcholine, isolated from pig brain extracts[13], is a very poorly active cholinergic compound compared with ACh. It is not hydrolysed by AChE and is only poorly hydrolysed by PsChE. Its exact function is unknown but it is possible that it is a functionless by-product of the choline ester synthetic pathway.

Laminarinases in Soil and Litter Invertebrates

Laminarinases, enzymes hydrolysing β-D-(1→3)-glucans, are widely distributed among micro-organisms[1–3]. Chesters and Bull[1,2] examined their occurrence in 160 fungi. Eighty per cent of the species showed laminarinase activity. Fifty-six per cent of them had laminarinases of the endohydrolytic type (yielding laminaridextrins as initial products), 25 per cent of the exohydrolytic type (yielding glucose as the sole initial product and only later laminaridextrins), and 19 per cent were intermediary, with both laminarinase types.

The presence of laminarinase in the digestive tract of animals has received little attention. Myers and Northcote[4] report a powerful laminarinase from *Helix pomatia*, and Bailey and Clarke[5] from *Entodinium* species of the sheep rumen.

Since, however, snails and slugs seem unique among soil and litter animals in possessing a very wide range of carbohydrases hydrolysing polysaccharides[6] a number of soil and litter invertebrates of widely different systematic position and feeding types were tested for laminarinase activity: Oligochaetes: *Cognettia sphagnetorum* (Vejd.), *Lumbricus rubellus* Hoffm., *L. terrestris* L.; Isopods: *Porcellio scaber* Latr.; Chilopods: *Lithobius forficatus* Koch; Diplopods: *Schizophyllum sabulosum* (L.), *Glomeris marginata* Koch; Insects: *Ectobius silvestris* (Poda), *Pterostichus niger* Fabr., *Philonthus* sp., *Phyllopertha horticola* L.; Gastropods: *Arion ater* L., *A. circumscriptus* Johnst.

Homogenates of guts and gut contents were extracted in phosphate–citric acid buffer, *p*H 4·95, and used as a source of enzymes, insoluble laminarin (Light and Co.) as a substratum. The products of hydrolysis were identified by paper chromatography.

All species showed very strong laminarinase activity yielding glucose as the main product of hydrolysis.

Two samples of laminarinase, associated with other enzymes, were obtained as an almost white powder by half-saturating the homogenates of *Arion circumstriptus* and *Porcellio scaber* with ammonium sulphate, centrifuging, dialysis against tap water, precipitation of enzymes by double the volume of acetone at 0° C, and redissolving the dried powder in water.

Dominant activities of the enzyme solution were laminarinase and β-glucosidase. Laminarinase activity extends over the *p*H-range 2·25–7·6 but is very weak below *p*H 3·0 and above 7·4. The activity curve is unimodal with a peak at *p*H 4·9–5·1 (*Arion circumscriptus*) or 5·2–5·7 (*Porcellio*). The dominant constituent of the laminarinase is of exohydrolytic type yielding large amounts of glucose and only traces of intermediary products (R_{gl} 0·81 and 0·43, descending chromatography, ethyl acetate/pyridine/water, 12 : 5 : 4).

The experiments suggest laminarinases to be widely distributed among soil and litter invertebrates.

Role of Catalase and Peroxidase in the Metabolism of Leucocytes

Leucocytes are known to be rich in catalase[1] and myeloperoxidase[1–3], yet very little is known concerning the role of these enzymes in leucocyte metabolism. In a recent investigation by Iyer *et al.*[4], evidence was presented for the formation of hydrogen peroxide by guinea pig exudate leucocytes. An obvious physiological function of catalase or peroxidase, therefore, might be to regulate the intracellular concentration of hydrogen peroxide which, if allowed to accumulate, could become toxic to the cells.

In order to assess the role of catalase in the metabolism of leucocytes a relatively specific inhibitor of catalase activity, 3-amino-1,2,4-triazole (AT), was used. This compound has been shown to inhibit the catalase activity of liver and kidney but not of the erythrocyte[5,6].

In the work to be presented here the effect of AT on leucocyte catalase *in vivo* and *in vitro* in comparison with other tissues was examined. An attempt was also made to ascertain a role of catalase in respiration and aerobic glucose utilization of leucocytes.

Male guinea pigs of *NIH* strain, weighing 350–500 g each, were used. Liver and kidney homogenates were prepared as described previously[7]. Erythrocytes were obtained by centrifuging heparinized blood at 100*g* for 15 min. After removal of the plasma and buffy layer, the erythrocytes were washed with saline to remove any traces of AT, and then lysed in 49 volumes of distilled water.

Suspensions rich in polymorphonuclear leucocytes (80 per cent) were obtained from peritoneal exudates of guinea pigs injected intraperitoneally with 10 ml. of a 12 per cent solution of sodium caseinate 16–18 h prior to killing, as described by Stahelin *et al.*[8]. The leucocytes were removed from the exudate by centrifugation at 250*g* for 5 min, washed once with 5 ml. 0·9 per cent saline, and finally suspended in 1 ml. of distilled water and homogenized by 50 passes in a glass-'Teflon' homogenizer with a motor-driven pestle. For enzymatic assays the

homogenates were diluted with distilled water to a final volume of 10 ml.

Respiration and uptake of glucose were measured in Warburg flasks in air at 37° C as described previously[9]. For enzymatic assays the cells were collected quantitatively from the Warburg flasks at the end of the incubation period (2 h), washed once with 5 ml. saline and homogenized as described above for the *in vivo* investigations.

Catalase was assayed spectrophotometrically as described previously[7,10]. Myeloperoxidase was assayed using the guaiacol method, as described by Schultz, *et al.*[11].

Table 1. Effect of AT on Catalase Activity of Guinea Pig Liver, Kidney, Erythrocytes and Leucocytes *in vivo*

Tissue	Catalase activity Control	Catalase activity AT	Inhibition %
Liver*	666 ± 30 (9)†	15 ± 1 (9)	98
Kidney*	67 ± 2 (9)	6 ± 1 (9)	91
Erythrocytes‡	77 ± 9 (6)	75 ± 10 (6)	0
Leucocytes‡	46 ± 2·5 (4)	2 ± 0·7 (3)	96

* Catalase activity is expressed in units/g wet tissue.
† Mean ± standard error of the mean (number of observations).
‡ Catalase activity is expressed in units/ml. packed cells (1,000g/30 min)

The results of the *in vivo* experiments are summarized in Table 1. Injection of 1 g of AT/kg body weight of guinea pig, 12 h prior to death, produced 98 per cent inhibition of catalase activity of the liver, 91 per cent inhibition of the kidney catalase but was without any apparent effect on the erythrocyte catalase. These observations confirm the work of other investigators[5,6,12] who used different species, primarily rats and mice. AT also caused a profound depression of the leucocyte catalase (96 per cent), comparable to that seen in the liver.

Table 2. Effect of AT on Catalase Activity, Oxygen Uptake and Glucose Utilization by Leucocytes *in vitro**

AT concentration (M)	Catalase activity (units/ml. packed cells)	O_2 uptake (μl./h/10^7 cells)	Glucose utilization (μmoles/2 h/10^7 cells)
None	35·0	2·9	0·74
1×10^{-4}	32·5	2·7	0·73
5×10^{-4}	27·0	3·0	0·73
1×10^{-3}	20·0	3·0	0·69
5×10^{-3}	4·0	2·8	0·73
1×10^{-2}	3·0	3·0	0·69

* Each value represents the average of two determinations. The cells were incubated in the presence of 3 ml. Krebs–Ringer phosphate medium, *p*H 7·4, containing glucose, 5·6 μmoles/ml.

The leucocyte catalase was also markedly inhibited by AT *in vitro*, as shown in Table 2. The inhibition was proportional to the AT concentration used, the greatest effect being observed at 10^{-2} M (91·4 per cent) and the smallest at 10^{-4} M (7·1 per cent). The leucocyte preparations treated to remove the few contaminating red cells, by the method of Fallon *et al.*[13], had a level of catalase activity comparable to that seen in the untreated leucocytes.

Inhibition of the leucocyte catalase occurred regardless of whether glucose was present or absent in the incubation medium. Despite the marked effect on the leucocyte catalase activity, AT had no apparent influence on the leucocyte respiration rate and glucose utilization.

Leucocytes (3 different preparations) were also assayed for their myeloperoxidase activity, the mean ($\pm S.E.$) value of which was found to be $0{\cdot}15 \pm 0{\cdot}017$ μmoles of tetraguaiacol produced per min per 10^7 cells. The incubation of leucocytes with 10^{-3} or 10^{-2} M AT, in contrast to catalase, produced no apparent change in the leucocyte peroxidase activity.

On the basis of the evidence presented here with respect to the effect of AT on catalase activity of different tissues, it is evident that leucocyte behaviour is similar to that of the liver and kidney rather than to that of the erythrocyte. Tumour extracts, which are known to depress the catalase activity of the liver but not of whole blood, have also been reported to inactivate leucocyte catalase[14].

The work by Iyer *et al.*[4] suggests that hydrogen peroxide is generated in leucocytes as a product of glucose oxidation via the hexosemonophosphate shunt pathway. Our results also suggest that hydrogen peroxide is formed in leucocytes since the presence of hydrogen peroxide is a prerequisite for the inhibition of catalase by AT[12]. It is also apparent from the work recorded here that leukocytes lack the sulphydryl compound present in erythrocytes that prevents the inhibition of catalase by AT[15]. It is evident that the rates of oxygen and glucose uptake by leucocytes are relatively independent of catalase activity down to as little as 9 per cent of the original activity of this enzyme. It is possible that the residual catalase activity in the presence of 0·01 M AT is sufficient to protect the cell from hydrogen peroxide accumulation. However, a more likely explanation might be that some other hydrogen peroxide destroying system such as myeloperoxidase, which is found in high concentrations (5 per cent of the dry weight) in leucocytes[3], might be of greater significance than catalase in protecting the cell from any toxic effects of hydrogen peroxide. Further work will be necessary, however, before it will be possible to decide between these two alternatives.

Absence of Free Iodotyrosines from the Plasma of the Rat

Werner *et al.*[1,2] and Beale and Whitehead[3] have recently claimed to have demonstrated the presence under physiological conditions of free 3 : 5-di-iodotyrosine (DIT) and 3-iodo-tyrosine (MIT) in the serum of euthyroid human beings and rats using paper chromatographic separation followed by several methods for the detection and estimation of iodine[1–5], a distinctive feature of these serum iodotyrosines being that they could not be labelled with radioiodine.

From a physiological point of view, the existence of iodotyrosines in blood is difficult to understand because of the following facts: (1) the existence of an active iodotyrosine-dehalogenase in the thyroid gland[6]; (2) the very short half-life of injected radio-DIT (1·5 h) (ref. 7) correlated with the presence in many tissues and especially in liver and kidney of iodotyrosine-dehalogenases; (3) the impossibility of detecting DIT as a metabolic product of injected thyroxine labelled on the four iodine atoms[8]; (4) the inability of these serum iodotyrosines to be labelled after radioactive iodine administration.

By combining the isotopic equilibrium method[9,10] with the gel filtration of plasma[11] we have been able to demonstrate the absence of free DIT and MIT in the plasma of the rat.

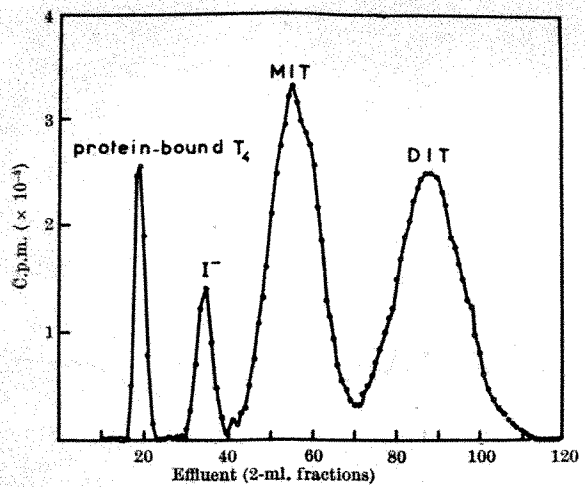

Fig. 1. Filtration on 'Sephadex *G*-25' of plasma supplemented with ^{131}I-labelled iodo-compounds. The gel was equilibrated with 0·2 M ammonium acetate *p*H 5·8 and the elution performed with the same buffer. Column size, 2·5 × 20 cm; fractions of 2 ml. collected at a flow-rate of 1 ml./min. 3 ml. plasma was supplemented with: $Na^{131}I$, 5,400 c.p.m. (tracer); ^{131}I-L-thyroxine, 8,500 c.p.m. (S.A., 25 μc./μg); ^{131}I-di-iodo-L-tyrosine, 47,200 c.p.m. (S.A., 18 μc./μg); ^{131}I-mono-iodo-L-tyrosine, 49,510 c.p.m. (S.A., 15·5 μc./μg)

Male rats (Wistar strain, average weight 280 g) fed on an iodine-free diet were given a regular daily dose of iodine in their drinking water in the form of $K^{127}I$. One group received 5 μg of iodine a day and a second one 50 μg. In animals previously treated in this way an isotopic equilibrium was reached after administration for 50 days of the same drinking water labelled with iodine-125 at a constant specific radioactivity, not however correcting for the decay of the radioisotope (0·10–0·15 μc./μg iodine on the first day according to the group). At isotopic equilibrium, each iodine pool has the same specific radioactivity as the drinking water. Thus, the iodine content of each pool may be calculated by the ratio of its radioactivity to the specific radioactivity of the drinking water.

Gel filtration of plasma was performed as previously described[11] using 'Sephadex *G*-25' equilibrated with 0·2 M ammonium acetate *p*H 5·8.

Fig. 1 shows the results of a gel filtration of rat plasma supplemented with iodine-131-labelled iodide, MIT, DIT and L-thyroxine.

The separation of iodotyrosines from iodide and protein-bound thyroxine is reproducibly unambiguous.

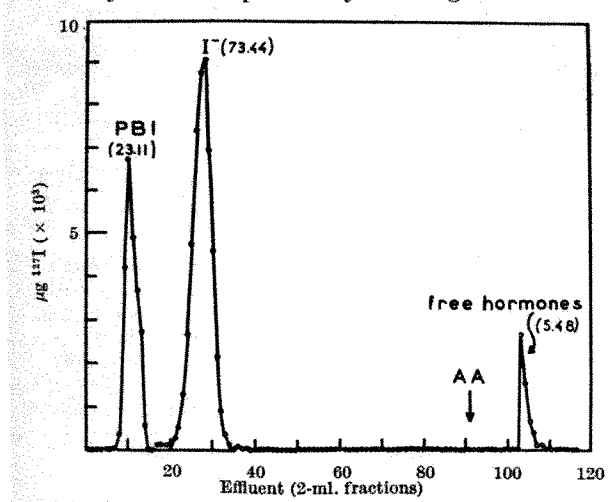

Fig. 2. Filtration on a 'Sephadex *G*-25' column (2·5 × 14 cm) of rat plasma (3 ml.). The sample was obtained from pooled plasma of five rats which were adapted to a daily dose of 5 μg of iodine and maintained in an isotopic equilibrium with iodine-125. Same conditions of buffer and elution as in Fig. 1. *AA* indicates the replacement of ammonium acetate by tertiary amylol saturated with ammonium 2 N. The figures indicate the total amount of iodine-127 calculated from the iodine-125 counting as explained in the text

Fig. 2 shows the analysis of a sample of the pool of equal volumes of plasmas obtained from 5 rats which were adapted to a daily dose of 5 μg of iodine and maintained in an isotopic equilibrium with iodine-125. No radioactivity is detectable in the eluates from the MIT- and DIT-zones.

Other experiments performed in the same way with rats adapted to a daily dose of 50 μg of iodine failed also to show the presence of both free MIT and DIT.

The conditions of isotopic equilibrium used in this investigation, the absence of any treatment of plasma before filtration on 'Sephadex *G*-25' and the good separation of iodotyrosines from iodide and thyroid hormones justify the conclusion that free MIT and DIT are not normal components of the plasma in the rat. Under the conditions of iodine-125-radioactivity counting used, as little as 0·0003 μg of iodine iodine-127 per ml. plasma would have been detected.

Pitt-Rivers and Rall[12], using isotope equilibrium for a shorter period in the rat and anion-exchange resin chromatography for the separation of iodo-compounds, have already concluded that the iodotyrosines were virtually absent in the serum.

Wellby and Hetzel[13] have also concluded that iodotyrosines are absent from the plasma of euthyroid human beings using anion-exchange resin and paper chromatography for the separation of iodinated compounds.

If technical artefacts are not concerned, two main possibilities offer themselves to explain the contrary results of Werner *et al.*[1,2] and Beale and Whitehead[3]:

(1) The degradation of plasma T_4 (and T_3) to DIT during extraction procedures; many oxidizing systems are indeed capable of breaking the diphenylether bridge of T_4 (and T_3); (2) the existence in the serum of DIT- (and/or MIT-) generating compounds which could be degraded into free iodotyrosines during extraction.

However, this does not explain why the iodinated compounds identified as iodotyrosines could not be labelled with radioiodine, a situation which is rather difficult to interpret on a physiological basis.

PHYSIOLOGY

Central Actions of Psychotomimetics

ALTHOUGH the alterations in human behaviour and mental activity produced by psychotomimetic substances are not necessarily closely related to those observed in the psychoses[1], the central modes of action of these substances are nevertheless of considerable interest. It is possible

that drugs chemically related to tryptamine, lysergic acid and the catecholamines block synaptic excitation in certain regions of the central nervous system, such as has been demonstrated in the lateral geniculate nucleus[2]. These substances may also mimic central inhibitory transmitters[3], since certain derivatives depress the excitability of neurones in the cerebral cortex and thalamus[4].

An interesting series of compounds with psychotomimetic properties are the piperidyl and pyrrolidyl esters of glycolic acid[5]. Although many of these substances have an atropine-like action on the human autonomic nervous system and block the excitant action of acetylcholine on smooth muscle *in vitro*[6], it has been considered unlikely that the central action of the glycolic acid esters is related to the central blockade of acetylcholine or an acetylcholine-like transmitter[5].

Recently it has been reported that *N*-methyl-2-pyrrolidylmethyl α-cyclopentyl-α-phenylglycolate affects the metabolic and functional properties of frog muscle[7]. In particular, at concentrations of 10^{-6} M, this psychotomimetic has a calcium-like action on the excitable membrane and renders it less excitable. Similar depressant actions have hitherto not been reported for nervous tissue[7] and the present results are concerned with the actions of *N*-ethyl-3-piperidyl α,α-diphenylacetate, *N*-methyl-3-piperidyl α,α-diphenylglycolate methochloride, *N*-methyl-3-piperidyl α,α-diphenylglycolate and *N*-ethyl-2-pyrrolidylmethyl α-cylopentyl-α-phenylglycolate upon mammalian neurones. Only the last two of these agents are psychotomimetics[5,6].

The extracellular spike potentials of single neurones in the spinal cord and thalamus of cats anæsthetized with pentobarbital sodium have been recorded by means of the central barrel of five-barrel micropipettes. The glycolic acid esters were ejected electrophoretically as cations from dilute solutions of the appropriate chlorides or hydrochlorides. Spike potentials evoked synaptically or by the electrophoretic ejection of acetylcholine (cation) or L-glutamic acid (anion) were photographed or counted by means of a rate meter and the frequency of firing displayed on a paper recorder. The effect of *N*-ethyl-2-pyrrolidylmethyl α-cyclopentyl-α-phenylglycolate ('*JB* 8099') upon the responses of a spinal Renshaw cell is illustrated in Fig. 1. The frequencies of firing evoked by L-glutamic acid and acetylcholine were approximately equal, but the electrophoretic ejection of '*JB* 8099' depressed the acetylcholine-firing to a greater extent, and for a longer time, than the amino-acid induced firing. Simultaneously (Fig. 1*B*) there was a reduction in the number of repetitive spike potentials elicited by orthodromic stimulation of the cell. All of these agents had a similar action when tested upon Renshaw cells and upon cholinoceptive thalamic neurones[8], and it was usually possible with small electrophoretic currents to reduce selectively the rate of firing produced by acetylcholine without affecting that produced by an excitant amino-acid. Furthermore, the excitation of non-cholinoceptive spinal interneurones by acidic amino-acids was readily reduced by these esters, thus indicating a reduction in the excitability of the post-synaptic membrane of these cells, possibly by a mechanism similar to that proposed for frog sartorious muscle[7]. The actions of all of these substances are thus similar to those of procaine, atropine, hyoscine, benactyzine and 1-(1-phenylcyclohexyl)-piperidine[9].

It is difficult to relate the concentrations of these substances attained electrophoretically to those obtained by systemic administration. However, the results demonstrate that these substituted piperidyl and pyrrolidyl glycolates can reduce the excitability of central neurones and also antagonize the action of acetylcholine upon cholinoceptive neurones. Such effects upon electrically excitable membrane and acetylcholine receptors appear to be common to many agents having local anæsthetic or atropine-like actions. It is possible that alterations in human behaviour and mental activity may be produced in

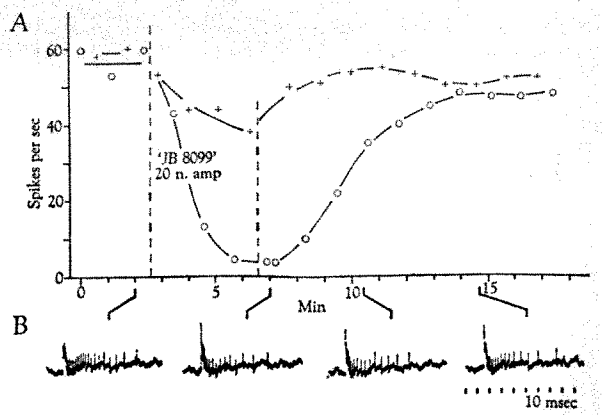

Fig. 1. *A*, Extracellular spike responses of a single Renshaw cell were counted by means of a rate meter and the symbols indicate the maximal frequency of firing evoked by alternating 15 sec ejections of L-glutamate (+) and acetylcholine (○) using electrophoretic currents of 70 n.amp and 10 n.amp respectively. Between the vertical broken lines '*JB* 8099' was ejected from another barrel of the five-barrel micropipette, using a current of 20 n.amp. *B*, Synaptic responses of the same Renshaw cell, recorded during the series plotted in *A*, and evoked by maximal stimulation of the segmental ventral root. The lines indicate the times at which these responses were photographed. Time, 10 msec

at least three ways, if and when these glycolic acid ester reach central neurones. In the first place transmission i small diameter presynaptic fibres may be modified c blocked, thus affecting transmitter release at centra synapses. Secondly, the depression of neuronal excita bility can affect the repetitive responses of nerve cells t synaptic stimulation. Thirdly there may be antagonism towards the synaptic action of acetylcholine; and in thi respect the degree of antagonism of these agents toward acetylcholine upon smooth muscle may not necessarily b related to this central action.

We thank Dr. L. G. Abood for samples of the glycoli acid esters used in this work.

Anorexic Effect of Intraperitoneal Glucose in the Hypothalamic Hyperphagic Cat

In previous communications[1,2] one of us reported result leading to the hypothesis that peripheral glucoreceptor (hepatic and, perhaps, muscular) play an important par in the regulation of intake of food. The classical gluco static theory of the regulation of intake of food[3] postulate that the ventromedial hypothalamic area has a mechanism for glucostatic regulation of appetite and feeding. Th lack of ventromedial glucoreceptors is regarded b proponents of this theory as being instrumental in th development of the hyperphagia observed when th ventromedial hypothalamus is lesioned bilaterally. Thi communication presents data concerned with the possibilit of glucoreceptors regulating appetite as being locate elsewhere than in the ventromedial hypothalamic area.

A total of 23 experiments were performed in 2 adul cats weighing 2·8 and 3·4 kg respectively at the beginnin

of the work. In these two animals bilateral ventromedial hypothalamic lesions were electrolytically produced. Following these lesions both cats became hyperphagic, increasing their weights by 1·1 and 1·4 kg in the first month post-operatively. Intraperitoneal glucose injections in doses of 0·4–2·0 g/kg were administered during the active phase of hyperphagia. The injections were administered in a sound-proof chamber via a polyethylene tube attached to a syringe on the outside. The injection needle was fixed in place by means of an abdominal belt at the beginning of the experiment, thus avoiding extraneous stimulation during the actual entrance of the solution. The animals were always tested after a 12–24 h fast. Four adult intact cats served as controls.

In a control period of several test days the hyperphagic cats were observed to consume freely more than 10 approximately 10-g portions of raw horse meat given at 1–3 min intervals. Often these animals ate more than 200 g of meat before showing any signs of satiation.

When glucose was injected in sufficient doses (0·6–1·0 and 1·0–2·0 g/kg respectively) the cats refused to feed for periods of 15–45 min after having eaten only 2 or 3 portions preceding the injection. After this period of time had elapsed the animals began first to feed irregularly and finally with the usual voracity. The latency of this anorexia was 1–2 min in the first cat and 1·5–4 min in the other. Smaller doses of glucose (0·4–0·5 and 0·8–0·9 g/kg) did not inhibit intake of food, thus providing suitable controls showing that entrance of the hypertonic solution into the peritoneal cavity does not in itself produce anorexia.

In the 4 intact cats the minimum intraperitoneal doses of glucose producing anorexia were from 0·5–0·9 g/kg. The latency in these animals varied between 1 and 3 min and the anorexia persisted for 10–25 min. Thus, the sensitivity to glucose of the cats deprived of the ventromedial hypothalamic area is not significantly different from that of intact animals, and the anorexic effect seems to be even more prolonged.

At the completion of the experiments, the brains of both cats were perfused *in situ* with 10 per cent formalin, frozen, and sectioned at 40μ, and stained by the Kluver–Barrera method, in order to identify the symmetry, extent, and location of the lesions. Fig. 1 shows the lesions in one of the cats.

The foregoing results provide some evidence for the existence of glucoreceptors outside the ventromedial hypothalamic area. Integrating these findings with the presumed organization of the hypothalamic 'appestat', our hypothesis assumes that a tonic discharge originating in hepatic, and perhaps muscle glucoreceptors, might be responsible for the tonic activity of the lateral hypothalamic 'feeding centre'. This discharge should decrease when intracellular glucose or some related metabolite increases in hepatic and muscle cells. It is possible that the ventromedial hypothalamic 'satiety centre' represents an inhibitory loop functioning in a manner similar to inhibitory loops from caudate and red nuclei on muscle tonus. When these inhibitory loops are suppressed the excitatory mechanisms are liberated producing exacerbated reactions such as decerebrate rigidity or hyperphagia. Peripheral glucoreceptor signals may inhibit the 'satiety centre' as well as excite the 'feeding centre' directly. A small reduction of these signals could liberate the satiety mechanisms thus inhibiting the activity of the 'feeding centre' in addition to diminishing the direct excitatory input to the 'feeding centre'. When the 'satiety centre' is removed the decrease in peripheral glucoreceptor signals produced by feeding is no longer sufficient to suppress activity of the 'feeding centre' since the inhibitory loop is lacking, thus resulting in hyperphagia. However, a stronger reduction of these signals as produced by a large dose of glucose going directly to the liver results in a sufficient reduction of the excitatory input to the 'feeding centre' to provoke anorexia, both in the normal intact and hypothalamic hyperphagic animal.

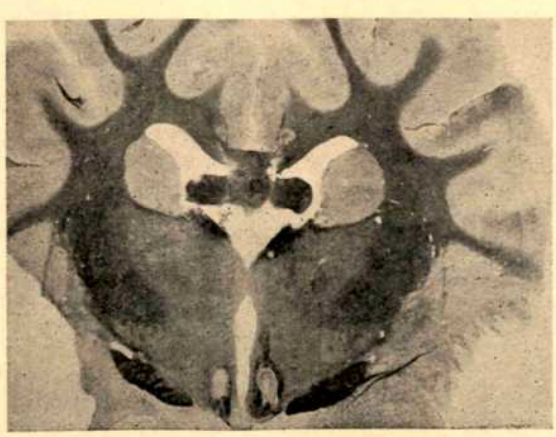

Fig. 1. Frontal section through the brain of the cat at anterior stereotaxic plane 12·0 indicating the bilateral electrolytic lesions in the ventromedial hypothalamic area

HISTOLOGY

Localization of Anti-human Growth Hormone Serum within the Human Placenta: Evidence for a Human Chorionic 'Growth Hormone-prolactin'

Josimovich and MacLaren[1] have recently reported the presence in human placenta of a component which cross-reacts with rabbit anti-human growth hormone serum. This protein, which gave a reaction of partial identity with human growth hormone, exhibited prolactin activity and was detected in peripheral venous serum at term and in retroplacental serum by the Ouchterlony gel diffusion technique. Further immunochemical, physicochemical, and biological characterization of this cross-reacting placental protein, detectable in fresh saline homogenates of human and simian placenta, has been described by Kaplan and Grumbach[2]. Immuno-electrophoresis in agar gel (barbital buffer, *p*H 8·2) and starch gel electrophoresis (discontinuous buffer system of Ferguson and Wallace) indicate that the migration of the placental component differs from that of native and purified human growth hormone. A partially purified preparation of the cross-reacting placental component contains significant growth-promoting activity[2].

Localization of fluorescein-labelled rabbit anti-human growth hormone serum has been demonstrated in the acidophils of the human anterior pituitary gland and in eosinophilic adenomas associated with acromegaly[3,4]. In view of the evidence indicating a protein in human and simian placentæ which partially cross-reacts with rabbit antiserum to human growth hormone, the Coons labelled antibody technique[5] was applied to determine the localization of this component within the human placenta.

Representative areas of the villous portion of first, second and third trimester human placentæ were processed

by the freeze-drying method and sectioned at 1·5μ. Cryostat sections of fresh tissue and formalin fixed deparaffinized sections gave the same localization of fluorescence, but the specificity of the cytological detail was superior in the freeze-dried material and this was used for most observations. Both the indirect and the direct immunofluorescent techniques were employed. For the indirect technique fluorescein conjugated sheep anti-rabbit γ-globulin (SA-RGG-F) was used, while for the direct technique a highly potent anti-HGH[6] was conjugated with fluorescein isothiocyanate (A-HGH-F). Fluorescein conjugated antisera were purified further by filtration through a 'Sephadex *G*–25' column. The antisera were absorbed with rat and rabbit liver powder. Sections were incubated for periods of time varying from 45 min to several hours, and then viewed under the standard fluorescence microscope. Placental autofluorescence was not a complicating factor. Heterologous tissue controls and heterologous antibody controls were performed. Absorption of the conjugated antiserum with HGH abolished the specific fluorescence and pre-incubation of the tissue sections with unlabelled anti-HGH blocked the specific fluorescence of A-HGH-F used in the direct procedure.

Multiple sections from six placentæ were examined, ranging in gestational age from 12 weeks to term. In all instances specific fluorescence was localized to the cytoplasm of the syncytiotrophoblastic villous epithelium. Fluorescence was not present in the cytotrophoblastic layer. Cytoplasmic fluorescence was extensive and not localized to any specific sub-area of the syncytial cytoplasm, although occasional perinuclear areas and fragments of the syncytial brush border gave strong fluorescence. A section of a mid-trimester placenta is shown in Fig. 1 which illustrates fluorescence in two strips of adjacent syncytiotrophoblastic cytoplasm. Presented in Figs. 2*a* and *b* are phase contrast and fluorescence photomicrographs of the identical areas of a section of term placenta, again indicating fluorescence in the cytoplasm of the syncytiotrophoblast. Rabbit anti-human chorionic gonadotropin sera did not inhibit the fluorescence.

These findings indicate that the human placenta as early as the twelfth week of gestation contains a protein localized in the syncytial cytoplasm of the villous trophoblast which immunologically partially cross-reacts with rabbit anti-HGH serum. Studies to be reported[2] elsewhere suggest that this protein is a chorionic 'growth hormone-prolactin' and may represent an important metabolic hormone of pregnancy. It is noteworthy that immunofluorescent investigations of human chorionic gonadotropin in the human placenta by Midgley and Pierce[7] and similar investigations by Sciarra and Tallberg[8] indicate that this hormone is also present in the syncytiotrophoblast.

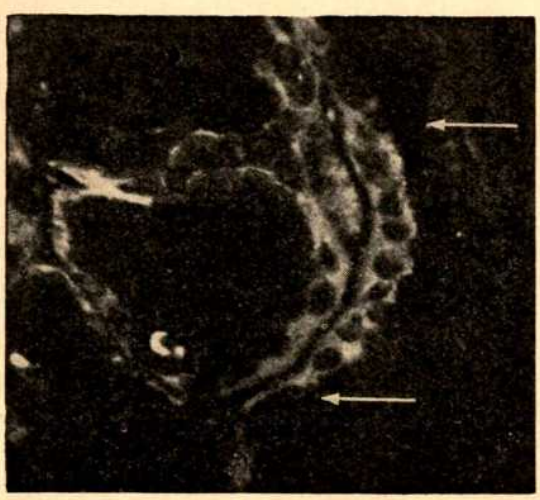

Fig. 1. Fluorescence photomicrograph of a section of a 19-week placenta prepared by freeze-drying and incubated with rabbit anti-HGH γ-globulin and subsequently with SA-RGG-F. The syncytiotrophoblastic cytoplasm exhibits marked fluorescence. Areas occupied by the syncytial nuclei are non-fluorescent. The location of non-fluorescent Langhans cells of the cytotrophoblast are indicated with arrows. (× *c.* 650)

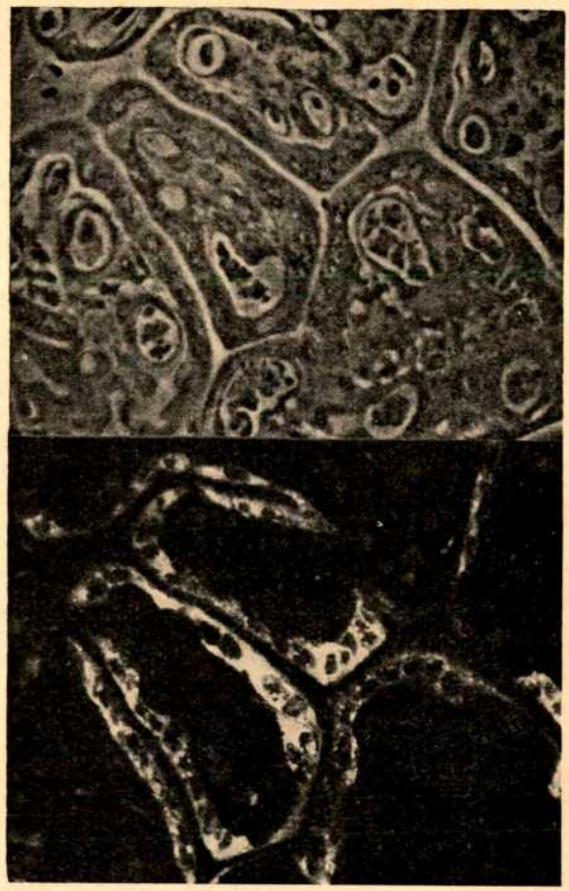

Fig. 2. *a*, Phase contrast photomicrograph of a section of the villous portion of a term human placenta prepared by freeze-drying. Notice the extensive layer of the syncytiotrophoblastic epithelium. Cells of the cytotrophoblastic layer, although rare, are present but are not identifiable at this magnification (× 500). *b*, Fluorescence photomicrograph of the identical area pictured above after incubation for 45 min with fluorescein-labelled anti-HGH illustrating the fluorescence localized to the cytoplasm of the syncytial layer of the villous trophoblast (× 560)

RADIOBIOLOGY

Barium Content of Different Parts of the Choroid of the Bovine Eye

Sowden and Pirie[1] analysed the barium and strontium content of different parts of the eye and confirmed earlier work showing that cattle choroid contained large amounts of barium. These authors did not, however, separate the tapetal fibres from the pigmented choroid and determine whether barium was also present in the tapetum. Weitzel *et al.*[2] have shown that zinc is an integral part of the tapetum of carnivores, and although the structure of the tapetum of the cow is quite different from that in carnivores we thought it would be interesting to determine whether there was any particular concentration of barium in the tapetum of the cow. This is a specialized part of the central choroid lying immediately under the retina and made up of fine parallel fibres which act as a diffraction grating and reflect light[3]. It is backed by pigmented choroidal tissue.

To separate the tapetal fibres, eyes from the slaughterhouse were opened by an equatorial cut and the front half, to which the whole vitreous body remains attached, was discarded. The retina was then removed leaving the choroid in position on the sclera and showing the tapetum as a brilliant blue-green area[4]. A cut was then made through sclera and choroid around the outline of the tapetum thus separating the choroid into tapetal and non-tapetal parts. The non-tapetal choroid was then scraped off the sclera and collected. The tapetal fibres were separated from the underlying choroid by gentle scraping with a scalpel under the dissecting microscope. The pigmented choroid underneath was then scraped off the sclera. Fig. 1 shows the tapetal fibres prepared in this way and then shaken in saline to get a fine suspension. They are remarkably uniform, a necessary attribute for fibres making a diffraction grating.

The three separated parts of the choroid were collected from several eyes and the barium in them estimated by activation analysis[5].

Samples were dried at 100° C for 12 h, weighed and transferred to a muffle furnace and ashed at 500° C overnight. Each ashed sample was powdered, mixed and weighed before being stored in a glass-stoppered bottle. An aliquot of about 5–20 mg from each ash was activated by irradiation in the Harwell pile. After irradiation barium was separated from the ash and the concentration estimated by comparison of radioactivity with that of the irradiated barium standard. The barium fraction was counted consecutively over a period (4 h) in a thallium activated sodium iodide crystal type gamma scintillation counter.

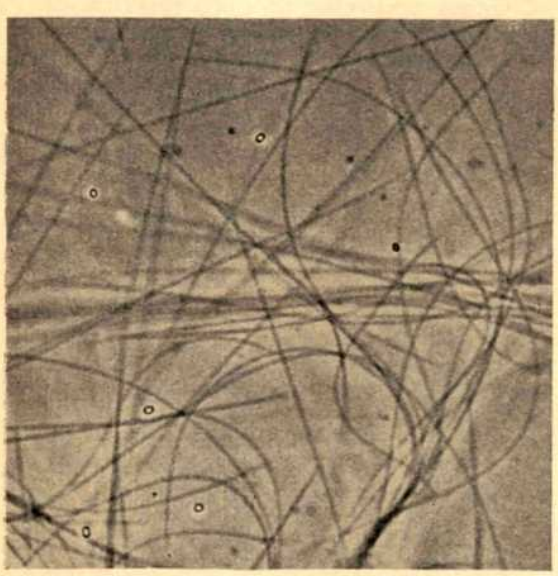

Fig. 1. Fibres of tapetum lucidum of cow. (× *c.* 890)

Table 1. Barium Content of Bovine Choroid and Tapetum

	Non-tapetal choroid	Choroid under tapetum	Tapetum
Cow			
mg Ba/100 g wet weight	97, 111, 91, 94·5	103, 93, 86, 95	17, 17, 17, 25
mg Ba/g ash	67, 76, 63, 71·5	84, 73, 76, 72	17, 17, 17, 27
Calf			
mg Ba/100 g wet weight	10·4	6·6, 5·9, 7·8	3·1
mg Ba/g ash	11·0	10, 9, 11·8	2·9

Table 1 shows that barium is associated with the pigmented choroid, not with the tapetal fibres. It appears to be distributed evenly throughout the pigmented choroid, whether this is under the tapetum or peripheral to it. The analyses confirm that the choroid of the cow is richer in barium than the choroid of the calf, nearing the extraordinary concentration of 1 per cent of the total ash. The human choroid normally contains traces of stable barium[1].

Garner[6] showed that when barium-140 was administered to cows it became concentrated in the choroid of the eye, the concentration reached being 10-fold that in the femur. Accumulation of barium-140 also occurred in the choroid of rabbits, animals which have no tapetum. It is possible that barium-140 produced in nuclear explosions concentrates in the choroid. Anderson[7] detected traces of barium-140 in deer in New Mexico, in a cow, and in milk samples in the United States. Since the half-life of barium-140 is about 12 days it will only occur in fall-out deposited shortly after an explosion. But that this can happen on a considerable scale was shown by Fisher *et al.*[8], who found that after the Russian nuclear explosions in the autumn of 1961, barium-140 contributed about 15 per cent of the total β-activity in air measured at Chilton, Berkshire. The maximum barium-140 on grass measured at the same place was 16,900 pc./m² in mid-November 1961. The fact that barium-140 is one of the more abundant fission products and that it becomes so markedly concentrated in the choroid of bovines makes it possible that this tissue should be considered when estimating the hazard from fall-out.

perforated polyethylene bags and half the tubers were irradiated with 10 krad of cobalt-60 γ-rays at the rate of 2·5 krad/min. One day after irradiation, half the irradiated and a similar number of control tubers were dipped in a 1,000 p.p.m. solution of methyl ester of indolyl-3-acetic acid (IAA) for 25 min. Simultaneously, the remaining tubers from both the irradiated as well as the control lots were dipped in distilled water for the same period. Tubers belonging to all the four treatments were afterwards stored at room temperature (23°–35° C; relative humidity, 50–85 per cent).

Irradiated, distilled-water treated potatoes were more susceptible to decay during the initial six weeks of storage (Table 1). Similar results were obtained by Rubin and Metlitsky[1] and Lewis and Mathur[2]. Treatment with methyl ester of indolyl-3-acetic acid resulted in a reduction in the decay rate both in irradiated as well as control tubers (Table 1). Physiological losses in weight (that i losses due to transpiration and respiration) were low in the potatoes treated with indolyl-3-acetic acid bo in irradiated as well as control lots (Table 2). Sproutir was completely prevented in the irradiated potatoe However, indolyl-3-acetic acid inhibited sprouting to considerable extent in control potatoes (Table 3).

Tomatoes. Tomatoes (var. 'Ox Heart') were picked i the green stage, packaged individually in perforate polyethylene bags and half of the fruits were irradiate with 10 krad of γ-rays at the rate of 2·5 krad/min. Ha of the fruits from each of the irradiated and the contr lots were dipped in a 1,000 p.p.m. solution of meth ester of indolyl-3-acetic acid for 25 min. Simultaneousl the remaining fruits from each of the irradiated and t control lots were dipped in distilled water for the sam period. The operations of picking, irradiation and trea ment with indolyl-3-acetic acid were done on the sam day. Fruits belonging to all the four treatments we afterwards stored at room temperature (24°–34° C relative humidity, 45–70 per cent).

The results obtained are recorded in Tables 4–6. Th rate of decay was the highest in irradiated, distilled-wat treated tomatoes, during the initial 20 days of storag Treatment with indolyl-3-acetic acid reduced very co siderably this initial high decay rate (Table 4). Th physiological losses in weight (that is, losses due to tran piration and respiration) were the lowest in irradiate indolyl-3-acetic acid treated tomatoes (Table 5). The ra of ripening was the slowest in irradiated, indolyl-3-aceti acid treated tomatoes during the initial 15 days of storag (Table 6).

It appears that γ-irradiation reversibly inactivat the endogenous indolyl-3-acetic acid synthesizing syste in the tomato fruits and potato tubers and that th effects of this inactivation can be counterbalanced b exogenous indolyl-3-acetic acid.

Changes occurring in the Excretion of Radiorubidium by Saliva in Rats after Whole-body Irradiation

Changes occurring in the excretion of electrolytes b saliva in irradiation sickness have so far received litt attention. In a previous report[1] we concentrated on th excretion of radiosodium by saliva in irradiated rats. I the work recorded here we investigated the excretion c rubidium the metabolism of which resembles that c potassium and which consequently occurs mostly in th intracellular compartments.

In the experiments to be reported use was made of 4 white rats of laboratory breeding divided into 4 groups c 10 animals. The rats were given water and a standar diet *ad lib.* All rats received concurrently 25 μc. rubidium 86/kg live body-weight, intraperitoneally, in 1 ml. c physiological saline. The first group served as a contro the remaining 3 were irradiated, 24 h following the admin istration of radiorubidium, with a dose of 1,000 r. c rœntgen radiation on the apparatus Makrophos, at 1 m.amp, 150 kV, filter 0·5 mm aluminium, 0·5 mm copper distance 120 cm. The dose rate was 10 r./min. In th individual experimental groups of rats, saliva was collecte under thiopental anæsthesia after the administration o pilocarpine at time-intervals of 6, 24 and 48 h followin

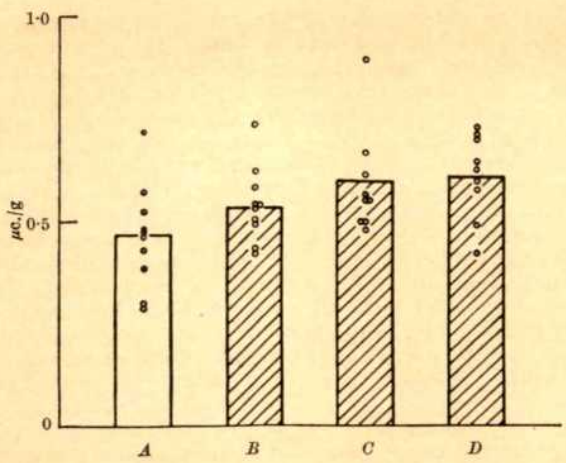

Fig. 1. Concentration of radiorubidium in saliva after irradiation (μc./g dry weight). *A*, Control group; *B*, 6 h after irradiation; *C*, 24 h after irradiation; *D*, 48 h after irradiation

irradiation. In the control group, saliva was collected in a similar fashion. The collection technique, according to Bernard *et al.*[2], was the same as that utilized in our previous investigation[1]. The samples of collected saliva were dried and weighed and their activity determined by measuring with a window Geiger–Müller tube for the measurement of β-activity using a standard.

From the resulting values the concentration of radio rubidium in the samples of saliva was determined in μc./g dry substance. The results, after correction has been made for excretion equally as in the previous investigation[1], are shown in Fig. 1. The heights of the columns express the mean values of radiorubidium concentration found in the individual groups, the points represent individual values. The column *A* belongs to the control group, the columns *B*, *C* and *D* consecutively to the groups of animals in which saliva was collected, respectively, 6, 24 and 48 h following irradiation. The last 2 columns include only 9 individual values since in each of the corresponding groups 1 animal had succumbed prior to the collection of saliva.

From Fig. 1 it is obvious that there occurs, after irradiation, in all the groups examined an increase in excretion of radiorubidium by the saliva as compared with the controls. On statistical evaluation we have found that the probability of insignificance of the differences in the values found in the controls and in the individual irradiated groups was: 6 h after irradiation more than 5 per cent, 24 h after irradiation less than 2·5 per cent, and 48 h after irradiation less than 1 per cent.

The significant increase in excretion of rubidium by saliva occurring 24 and 48 h after irradiation may be explained by a rise of its concentration in blood. It is known that the excretion of the analogous element potassium by saliva is directly dependent on its concentration in blood[3], and that there occurs, after irradiation, potassium depletion from a number of organs and consequently a rise in its blood-level[4].

BIOLOGY

Root Hair Zone of Soil-grown Roots

Pathogens which invade the roots of higher plants from the soil, in general, enter through the root hair zone of the seedling or the feeder roots of the older plant. Recent examination of certain common soil-grown species of dicotyledons and monocotyledons, namely, broad bean (*Vicia faba*), castor bean (*Ricinus communis*), mustard (*Brassica nigra*), purslane (*Portulaca oleracea*), radish (*Raphanus sativus*), squash (*Cucurbita pepo*), willow (*Salix* sp.), onion (*Allium cepa*), and wheat (*Triticum aestivum*), indicates that the description of the root hair zone in current text-books is inadequate and requires considerable modification in respect to the extent of the region of absorption and the details of tissue structure[1]. In present-day diagrams of the primary root, the root hair zone is invariably short. The xylem elements are devoid of contents. It is generally stated that the epidermis of the root differs from that of the shoot in the absence of a cuticle. It is somewhat difficult to reconcile the limitation of the absorptive region with the extent of the root systems which have been examined in detail by numerous investigators[2]. In rye grass, for example, the estimated total length of the $4{\cdot}5 \times 10^9$ root hairs amounts to 6,603 miles, with a surface area of 432 sq. ft. (ref. 3).

Extent of root hair zone. In dicotyledons the root hair zone, as described, occurs on the tap and lateral roots of the main root system which undergo secondary thickening. In addition, however, the absorptive region is supplemented by a wealth of slender filamentous roots which arise from tap roots and laterals, generally, but not invariably, in acropetal succession. In seedlings and in feeder roots these filamentous roots may measure 20 cm or more in length and are covered from tip to origin with living nucleated root hairs. Their increase in thickness is barely appreciable, with 2–4 xylem elements near the tip, and 6–8 at the point of origin. When filamentous roots first emerge on the root surface, the adjacent epidermal and cortical cells which have been forced apart are somewhat crushed but are already well cutinized or suberized. The healing of the surface tissue is thus concomitant with root emergence. Moribund roots become brown and somewhat shrunken and, after death and disintegration, a well-suberized root scar remains on the parent root until sloughed off during secondary thickening. The actual life duration of the filamentous roots is not known in the species examined.

In the soil-grown monocotyledons, onion and wheat, all the fibrous roots are much branched. The long and very slender laterals, like the filamentous roots of the dicotyledons, are covered throughout their length with living nucleated root hairs.

Epidermis. The surface of soil-grown roots is covered with soil particles, among which fungal hyphæ, bacteria and occasional other micro-organisms are visible. The walls of the epidermal cells, piliferous and non-piliferous, consist of a predominantly cellulose framework with a surface film of mucilage and a cuticle[4,5]. Pits and plasmodesmata occur on radial and periclinal walls, and, under the electron microscope, are evident also in the root hairs[6]. In the outer tangential walls the plasmodesmata appear to be anchored in the cuticle. The epidermis of the monocotyledons examined resembles that of the dicotyledons.

For comparison with soil-grown roots, those of a willow which extended from a stream bank into running water were studied. They resemble soil-grown roots in the presence of mucilage and a cuticle on the outer epidermal wall, including the root hairs.

The outer epidermal wall of the root is thus a complex stratified and perforate membrane. The plasmodesmata presumably play a part in the absorption of solutes and in the transport of the precursors of mucilage and of cutin essential during the growth in thickness of the wall, and

Fig. 1. Filamentous root of radish, living material slightly crushed, stained neutral red, showing protoplasts in the xylem elements, the diameter of which ranges from 3 to 5μ. The root hairs are not in focus

also in the exudation of specific substances in certain plants.

Cortex. Near the root tip, the meristematic cortical cells are polyhedral and are pitted on all cell faces. In the root hair zone the mature cortical cells are cylindrical or ellipsoidal and are partially separated by intercellular spaces. Intercellular contact is maintained through larger and comparatively fewer pits and plasmodesmata which are aligned vertically in 5 or 6 rows on the cylinder[7]. The ubiquitous pitting in the circular end walls is similar to that in the meristematic cells. Intercellular spaces arise as soon as cell growth in volume begins and the cell corners of the polyhedral cells are rounded off. The spaces form a continuum throughout the plant and the entire surface is coated with a lipid film, termed 'suberin' in this and in previous papers[9].

Endodermis. The innermost layer of the cortex has been discussed by many investigators, including Priestley[10], in relation to the entrance of water into the stele. More recently, Van Fleet has considered the significance of the biochemical changes which occur during differentiation[11]. Pits and plasmodesmata are numerous in the outer and inner periclinal walls and are also evident on the radial walls. In the latter, however, under the electron microscope, the pits and plasmodesmata are seen to be partially or completely embedded in the Casparian strip, a fact which explains the characteristic pattern of plasmolysis in the endodermis. The outer and inner rims of the Casparian strip are first delimited as fine lines of thickening on the radial walls next to the air-filled intercellular spaces. It therefore appears that suberin deposition begins next to the intercellular spaces and coincides with the initiation of wall thickening.

Pericycle. The pericycle is responsible for the origin of branch roots. The details of root initiation have not been worked out in the species at present examined, but they presumably resemble that of the strawberry[12].

Stele. During stelar differentiation, annular and spiral cells with pitted walls[13] are followed by reticulate and pitted vessel elements. These elements range in length from 50 to 1,000μ and in diameter from 4 to 25μ. In the transparent, filamentous, living roots, 2–4 annular or spiral elements are seen near the tip. Slight pressure frees the entire stele from the enveloping cortex. With or without the addition of neutral red or other aqueous stains, the majority of the xylem elements are seen to contain living nucleated protoplasts (Fig. 1). Isolated protoplasts with their projecting plasmodesmata are demonstrated when xylem elements, unlignified, or semi-lignified are treated with $I_2KI—H_2SO_4$ with the resultant disintegration of the cellulose walls[14]. In older roots the empty xylem elements are lined with a suberin film similar to the osmiophilic membrane or the warty layer of other authors[15,16]. It is thus evident that water and solutes pass directly into living protoplasts in the root hair zone, from which they are released into the transpiration stream on the death of the xylem protoplasts at a higher level in the root.

In conclusion, the extent of the root hair zone, the cuticle of the outer epidermal wall, the lipid 'suberin' coating of all intercellular spaces, the pitting of all cell walls including root hairs and xylem elements, and the presence of living protoplasts in the xylem elements require consideration in relation to absorption of solutes, root exudation, the invasion of pathogens into living cells, and the transport of certain viruses.

A New Cycadeoid Plant from the Permo-Carboniferous Coal Measures of the Transvaal

A portion of a slender stem, with two pedicellate flower-like structures in organic attachment, shown two-thirds natural size in Fig. 1, was recently discovered in Lower Permian beds at Vereeniging, Transvaal. Remains of *Glossopteris* spp. leaves and a petiole of a leaf of *Noeggerathiopsis* sp. occur on the same slab of red ferruginous shale. The original organic material was replaced by ferric oxide and the plant is preserved in the form of a compressed cast of red ochre.

The much-flattened slender stem is striated longitudinally and has a uniform width of 6·5 mm. The thickness is approximately 1·5 mm which is also the total thickness of the woody zone surrounding the central pith, which is not preserved.

One of the two solitary and alternately arranged fructifications, shown near the upper end of the stem, is badly damaged and provides little detail. The more conspicuous second specimen, lower down the stem, is beautifully preserved, however. The axis of this flower-like structure is composed of a fleshy receptacle, borne on a strong woody pedicel, which is swollen in the region of its junction with the receptacle. The presence of the latter is inferred from

Fig. 1

the swollen nature of the basal portion of the structure. The true nature of the receptacle is unknown since it is obscured by a whorl of petal-like organs inserted round the base; apparently in several series.

There is a gradual decrease both in the width and thickness of these organs towards the apices and there are indications that they were traversed longitudinally by several vascular strands.

The general appearance of the fructification is that of a hypogenous angiospermous flower in which there is no distinction of calyx and corolla. Among fossil plants the fructification is reminiscent of the bisexual flowers of *Williamsoniella*. Whether the petal-like structures and receptacle of the new fructification actually functioned as staminate and ovulate organs, respectively, remains an open question, however.

Large flower-like fructifications, referred to the Bennettitales, were recently described by Plumstead[1] from the same beds in which the new plant was discovered. Although the two plants were evidently related, the former differed from the latter in that the flowers were much larger and were borne on very thick stalks.

The new plant has not been studied in detail yet, but the small size and general appearance of the flower in addition to the slender stem suggest classification under the Microflorae. The preliminary evidence afforded by the external morphological features seems to carry sufficient weight to suggest the separation of the plant, not only specifically, but also generically, from the known cycadeoids.

A Sensitive Method for Determination of Low Concentrations of Diquat and Paraquat

Determination of residues has become an important aspect of herbicidal research. Efforts are continually being made to increase the sensitivity of known tests for the chemical analysis of a large number of herbicides. Aquatic herbicides must be effective and used in small quantities (usually 1·0–5·0 p.p.m.) to be economically feasible; consequently, their residues are usually very small.

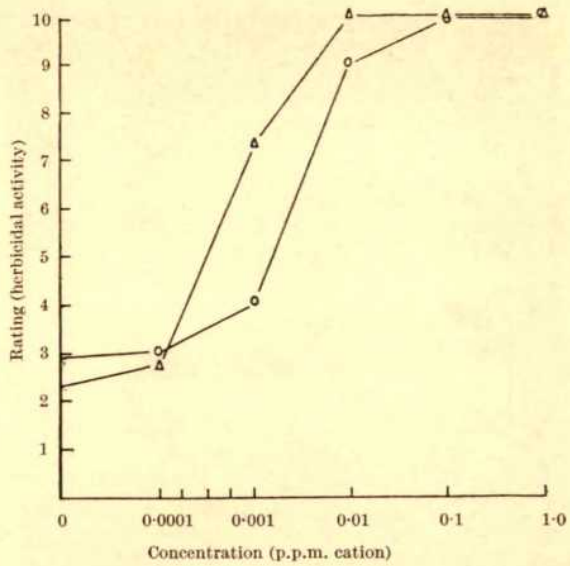

Fig. 1. Effect of various rates of diquat and paraquat on the chlorosis of duckweed. △, Diquat (11 days); ○, paraquat (11 days)

New herbicides which control a number of aquatic weeds at exceedingly low rates are 1,1′-ethylene-2,2′-bipyridylium dichloride (diquat) and 1,1′-dimethyl-4,4′-bipyridylium dichloride (paraquat). In preliminary experiments, it was observed that these chemicals caused a general and finally complete chlorosis of several aquatic weeds. One of the weeds, which was completely bleached by these herbicides, was duckweed (*Lemna minor* L.)[1]. This communication presents evidence of the extreme sensitivity of duckweed to diquat and paraquat.

All experiments were conducted in a growth-chamber where the conditions were as follows: 500 ft.-candles of light, 75° F, 14-h day and a 10-h night. Test plants were maintained in the same growth-chamber. They were grown in aerated 0·1 strength Hoagland and Arnon's No. 2 nutrient solution in a plastic dish-pan which measured 14 in. × 10 in. × 8 in. A 2-in. layer of sand and soil (50–50 mixture) covered the bottom of the dish-pan. A chelated source of iron was added periodically.

Approximately 50 fronds of duckweed were placed in each of nine 400-ml. clear plastic cups which contained 50 ml. of 1·0, 0·1, 0·01, 0·001, 0·00075, 0·0005, 0·00025, 0·0001, and 0 p.p.m. (cation) (since the cation is the herbicidally active portion of the molecule, all data are presented in p.p.m. cation) of either diquat or paraquat. The plastic container was covered with a clear, plastic lid. The condition of the duckweed was rated every 24 h for 11 days by the following system: 1–3 = control, 4–6 = herbicidal activity, 7–9 = definite herbicidal activity, and 10 = dead. Each test was duplicated and then replicated four times.

The effect of *p*H on herbicidal activity was also checked. Fifty ml. of a 0·01 M phosphate buffer (KH_2PO_4 for *p*H's 4–6 and K_2HPO_4 for *p*H's 7–10) which contained 0·1 p.p.m. diquat or paraquat was used for this work. The check was buffered at *p*H 7. The condition of the fronds was rated every 24 h for 3 days.

Duckweed was very sensitive to diquat and paraquat (Fig. 1). The bleaching effect caused by 1·0 p.p.m. is very rapid (24 h), while the appearance of chlorosis in plants subjected to decreasing rates of herbicide required a longer period of time. The herbicidal activity ratings for both chemicals at the end of 72 h was high for concentrations of 0·01, 0·1, and 1·0 p.p.m. It takes considerably longer (approximately 8 days) before the effect of the lower rates becomes evident. From the

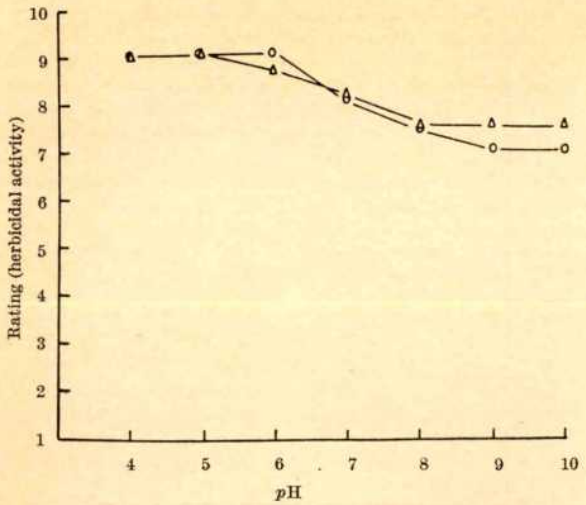

Fig. 2. Effect of diquat and paraquat on the chlorosis of duckweed at various *p*H's. ○, 0·1 p.p.m. diquat (72 h); △, 0·1 p.p.m. paraquat (72 h)

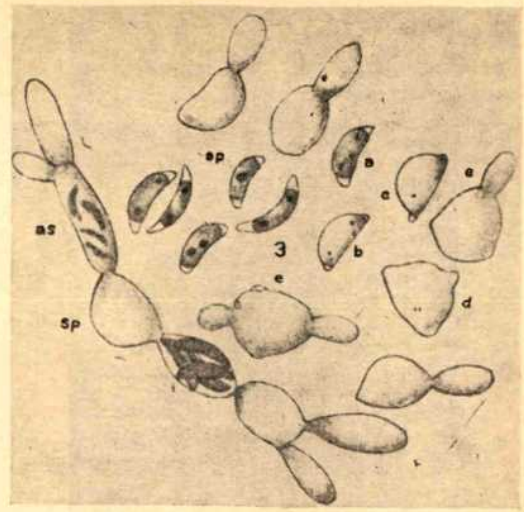

Fig. 1. *Guilliermondella selenospora*, from Nadson and Krassilnikov (ref. 1)

results presented in Fig. 1, it appears that 0·0005 p.p.m. diquat and 0·00075 p.p.m. paraquat can be detected by bioassay with duckweed. The sensitivity of this test is as good or better than many of the more common bioassays[2–5]. There is an excellent analytical procedure for determination of these compounds[6], but it has a maximum sensitivity of 0·01 p.p.m. The best results from this bioassay have been obtained when test plants from a young, actively growing culture were used.

The bleaching effect by both herbicides was more rapid at lower *p*H's (4–6) than at higher *p*H's (8–10) after 72 h. Forty-eight h later, or after a total of 120 h, no difference among the various *p*H's could be detected. The masking of the *p*H difference with time was expected, since 0·1 p.p.m. is a rather high concentration for this sensitive bioassay (Fig. 1). Diquat is unstable at high *p*H's, but paraquat is rather stable up to *p*H 11 (ref. 7). Therefore, the stability of these chemicals at various *p*H's does not explain the results presented in Fig. 2. The bioassay has been used to determine residues of diquat and paraquat in water collected from treated ponds and streams. It has also been used to detect the presence of these herbicides in the expressed cell sap from submersed aquatic weeds.

Ascospores of *Endomycopsis selenospora* (Nadson et Krassilnikov) Dekker

In 1928 Nadson and Krassilnikov[1] described a yeast isolated from the exudate of oaks in Kalouga, U.S.S.R. According to the original description, the yeast formed true mycelium as well as budding cells. Its asci contained four falcate spores. Nadson and Krassilnikov further stated that the ascospores appeared to have a double membrane, the latter being visible as two colourless appendages at the extremities of the spores (Fig. 1). On account of the characteristic ascospore shape the authors erected a new genus for this yeast and named it *Guilliermondella selenospora*.

Stelling-Dekker[2] transferred this species to the genus *Endomycopsis*, maintaining that *Endomycopsis* and *Guilliermondella* differed only in the shape of the ascospores, a criterion which she considered insufficient for separating these two genera. Stelling-Dekker's classification was accepted by Lodder and Kreger-van Rij[3].

The ascospore structure of *Endomycopsis selenospora* has recently been investigated in somewhat greater detail by ourselves. We have examined by means of the light microscope the spores of two strains of *E. selenospora* cultivated on malt agar and on corn-meal agar, and have been able to confirm Nadson and Krassilnikov's description. In several instances transparent appendages were visible at the extremities of the spores. However, there was considerable variation in spore shape. The spores, especially when still in the asci, may assume a more or less spheroidal to ellipsoidal shape. When liberated from the ascus the falcate shape was more pronounced, and so were the appendages.

An electron microscope examination of ultra-thin sections of the spores fixed with osmic acid and uranyl acetate according to the procedure described by Ryter

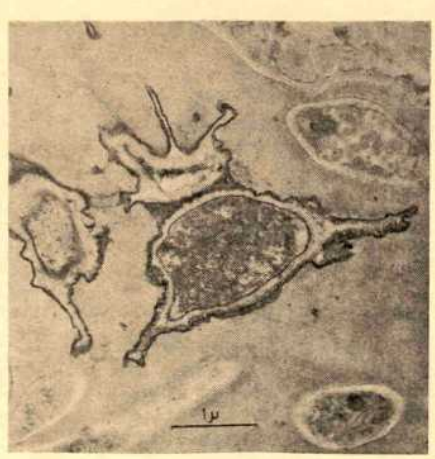

Fig. 2. *Endomycopsis selenospora*

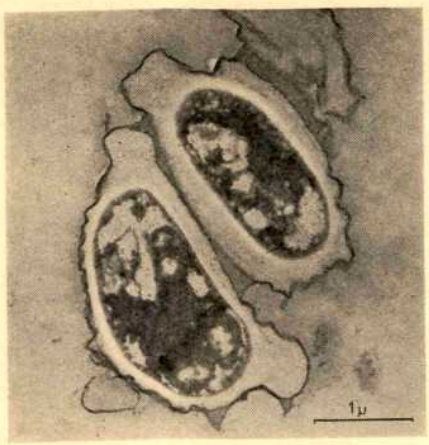

Fig. 3. *Endomycopsis selenospora*

et al.[4], revealed that the transparent parts were in fact outgrowths of the spore wall and comparable with the ledge structure on the spores of *Pichia* and *Hansenula* species. However, in the case of *E. selenospora* the outgrowths were restricted to the opposite poles of the spore and did not form circumfluent rims as is the case with the hat- or saturn-shaped spores of *Pichia* and *Hansenula*.

Cross-sections showed the spore wall either as a ring, more or less dented on the outside, or as a round to oval ring with two processes at the opposite poles (Figs. 2 and 3). The processes varied from thin protuberances of variable length to broad outgrowths.

Analogous investigations of the ascospores of other yeasts revealed that the internal structure of the spore of *E. selenospora* wall did not differ from that of, for example, *Saccharomyces* and *Pichia* species. The expression 'double membrane' does not, therefore, seem applicable to the spores of *E. selenospora*.

A comparison of the spores of *E. selenospora* with the crescentiform or reniform spores of *Sacch. fragilis* (Fig. 4) and *Sacch. delphensis* showed that in the last two species the spore wall had no outgrowths. The wall appeared thin and slightly notched, and this was also the case with the spores of *Sacch. cerevisiae* when observed under similar conditions.

Boidin *et al.*[5] have recently redefined the genus *Guilliermondella* so as to include budding yeast species forming 1–4 kidney- or crescent-shaped—more rarely spheroidal—ascospores which are liberated from the ascus at maturity. *Guilliermondella* would thus include, besides *E. selenospora*, species from the genera *Saccharomyces*, *Fabospora* and *Zygofabospora*.

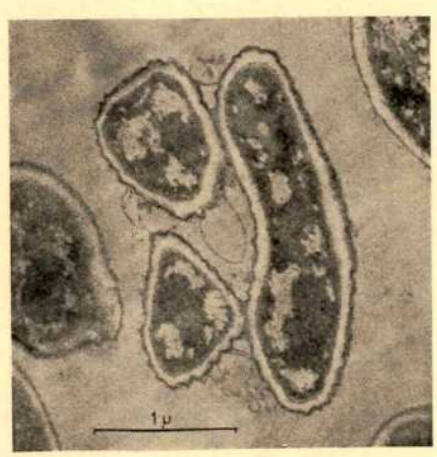

Fig. 4. *Saccharomyces fragilis*

From the findings we have described it is apparent that the resemblance in shape of the spores of *E. selenospora* to those of, for example, *Sacch.* (*Fabospora*) *fragilis* is superficial and does not constitute valid grounds for assigning *E. selenospora*, which produces an abundance of true mycelium, to a genus which, for the rest, consists entirely of budding species. We therefore regard *E. selenospora* as distinct from those species with crescenti- and reniform spores and which multiply exclusively by bud-formation, and prefer its provisional classification in the genus *Endomycopsis*.

We thank Miss J. M. Kempers for the preparation of the ultra-thin sections.

Effect of Scabs on the Rate of Epidermal Regeneration in the Skin Wounds of Guinea Pigs

The effect of scab on the healing of a wound is not well understood. MacCallum's[1] idea that the scab may store nutritive material for the granulation tissue is not generally accepted. James[2] demonstrated a high concentration of hydroxyproline in the scab hydrolysates but this was shown to be derived from the collagen fibres which had been incorporated into the scab[3]. Winter[4] put forward some experimental evidence designed to show that the scabs retarded the rate of epidermization of wounds in the skin of pigs. During an examination of the various factors which influence the rate of wound healing, observations have been made which are very different from those of Winter's.

Ten male guinea pigs, each weighing 200–250 g, were used. The skin of their dorso-lumbar region was shaved by an electric clipper. Twenty square pieces of rubber, each $3{\cdot}5 \times 3{\cdot}5 \times 0{\cdot}5$ cm in size, were taken and square holes of $2{\cdot}5 \times 2{\cdot}5$ cm were made into them. These rubber frames were used as splints. One of the splints was fixed in each flank of the guinea pigs by means of an adhesive paste. A wound of $1{\cdot}5 \times 1{\cdot}5$ cm was then made inside each splint. The wound area was first marked by a stamp and the skin was then removed along with the panniculus carnosus by means of a sharp scalpel, leaving deep fascia in the base of the wound. Immediately after a wound was made, its margins were traced on a tracing paper. Afterwards, a piece of polythene was fixed to each left-side splint in order to prevent drying of wounds on this side. The wounds on the right side were left uncovered. The animals were examined on alternate days and the wound margins traced again. The wound tracings were enlarged in an enlarger and retraced again on a Bristol board from which they could be cut out and weighed. By knowing the weight of the Bristol board per cm^2 it was easy to calculate the wound area.

The effectiveness of these splints in preventing wound contraction had been demonstrated in many experiments

Table 1

Days after wounding	Mean wound area with its standard deviation Left	Right
0	2·20 ± 0·06	2·21 ± 0·04
2	2·13 ± 0·11	2·09 ± 0·10
4	2·06 ± 0·09	2·00 ± 0·11
6	1·87 ± 0·12	1·68 ± 0·07
8	1·56 ± 0·10	1·49 ± 0·06
10	1·32 ± 0·07	1·31 ± 0·12
12	1·02 ± 0·07	1·10 ± 0·11
14	0·93 ± 0·12	0·88 ± 0·05
16	0·67 ± 0·13	0·75 ± 0·04
18	0·37 ± 0·05	0·43 ± 0·06
20	0·13 ± 0·08	0·20 ± 0·05

not mentioned here. It is therefore reasonable to assume that all these wounds healed almost exclusively by epidermization. The exposed wounds formed a dry and tough scab over them while the covered wounds had only a very thin and soft scab. Two of the covered wounds became infected—a phenomenon exceedingly rare in the exposed wounds of guinea pigs. Table 1 compares the mean area (with its standard deviation) of the left and the right side wounds on alternate days in eight guinea pigs. It is clear that there is no significant difference in the rate of wound healing on the two sides. The mean time taken by wounds to heal was 18·3 days on the left side and 18·5 days on the right, the difference being again insignificant.

A histological examination of both covered and uncovered wounds was also carried out in a separate experiment. It was found that even in an uncovered wound, where a thick scab formed, there was always a layer of fresh exudate under the scab. This exudation was a continuous process. The edge of the newly regenerating epidermis crept forward through this exudative layer and therefore encountered minimum resistance. It occasionally happened that the epidermal edge split into two branches, one spreading superficially and the other deeper to the scab. It was always the deeper branch which survived. In the uncovered wounds of the guinea pigs the first scab was usually discarded after the first five to seven days. A second scab promptly formed, but this again had a layer of exudate under it through which the epidermal edge continued its progress. Some necrosis of the wound edge always occurred[3] but this was traumatic in nature and had nothing to do with the drying of the wound. The epidermal edge seemed to have no difficulty in undermining this necrotic edge.

I thank Dr. A. H. T. Robb-Smith for introducing me to this subject, which is part of the work carried out during the tenure of a Rhodes Scholarship.

CYTOLOGY

Interaction of Chromatid Breaks induced by Three Different Radiomimetic Compounds

Quite a few physical and chemical inducers of chromosomal aberrations have been tested for interaction of chromatid breaks induced by different agents, the product of interaction being chromatid translocations (exchanges). On the basis of the breakage-reunion hypothesis presence or absence of interaction may be expected to give some hints on the bonds broken by the treatments being identical (full interaction) or not (no interaction, additive effect), provided time (different stages of maximal sensitivity against the agents) and space factors (different distribution of aberrations within and between chromosomes) can be ruled out as influencing the experimental results.

Table 1. Presence (+) or Absence (−) of Interaction of Chromatid Breaks induced by Different Agents in *Vicia faba* Root Tip Meristem

Table 1 summarizes the results of interaction experiments done by various authors using meristems of *Vicia faba* root tips as test materials for their investigations. Obviously it depends on the specific attributes of the agents combined or administered one following the other whether interaction of chromatid breaks induced by different agents appears or not. Both in combination experiments with X-rays and radiomimetic compounds or with different radiomimetic chemicals cases of interaction and non-interaction have been found (Table 1). Absence of interaction may be the result of various mechanisms[1–3].

We treated main root meristems of *Vicia faba* var. *minor* ('Dornburger Ackerbohne') with 5×10^{-4} M maleic hydrazide (MAL), 5×10^{-5} M triethylenemelamine (2,4,6-tri(ethyleneimo)-1,3,5-triazine, TEM) and 2×10^{-1} M ethyl alcohol (EA). Treatment time and temperature were 30 min. and 24° C in the first two cases and 4 h and 30° C in case of EA. Temperature during recovery time (time between treatment and fixation) was 24° C. Prior to fixation (3 parts ethyl alcohol, 1 part glacial acetic acid) the roots were immersed in 0·05 per cent colchicine for 2 h. Permanent Feulgen squashes were prepared by the dry ice method. The three agents, which are known chromosome breakers in *Vicia*[7–10], were administered one following the other. They are inducing preferentially localized aberrations on chromatid basis only, the distribution pattern of maleic hydrazide induced aberrations being characterized by significant differences in comparison with those of the two other agents. MAL, TEM and EA belong to the class of radiomimetic agents with delayed effects. No structural chromosomal changes can be observed the first 8 h after treatments with these agents. Thus it seems as if these compounds are unable to induce aberrations in cells where DNA synthesis is completed[11,12]. Different modes of action of MAL, TEM and EA are evident from experiments testing the influence of the metabolic state of the cells during treatment on aberration production.

The results of our experiments with the three compounds are given in Table 2 for 24-h recovery time which gave the

Table 2. Behaviour of Chromatid Breaks induced by Maleic Hydrazide (MAL), Triethylene Melamine (TEM) and Ethyl Alcohol (EA) in Exchange Production (400 Metaphases Scored, 24 h Recovery Time)

Treatment	Abnormal metaphases (%)	Isolocus breaks (%)	Exchanges % calculated Observed	additive	interaction
EA	18·25	9·75	6·75	—	—
TEM	12·25	7·75	4·0	—	—
EA—TEM	42·25	17·75	18·75	10·75	21·0
MAL	17·75	9·0	7·5	—	—
TEM	11·5	7·5	3·75	—	—
MAL—TEM	30·75	18·0	11·5		
TEM—MAL	30·0	17·25	11·25	11·25	21·5
EA	17·5	9·0	7·5	—	—
MAL	17·25	8·75	7·75	—	—
EA—MAL	27·25	15·0	13·25	15·25	30·5

aberration peak. Scoring of aberrations after 30-h recovery time gave lower aberration yields but the same results so far as interaction is concerned.

Interaction of chromatid breaks induced by EA with those induced by TEM is evident from Table 2. A comparison of the frequency of chromatid translocations (exchanges) scored and theoretically expected after treatment of root tip meristems with both EA and TEM indicates practically complete interaction of the breaks produced by the two agents. For isolocus breaks (intrachanges) the minimum expected frequency from the EA–TEM treatment would be that indicating additivity of the values found in the treatments with EA and TEM alone (controls) and this is, in fact, the case. From the interaction of chromatid breaks induced by EA and TEM it may be concluded that the breaks produced by these agents are of a similar or identical nature provided the breakage-reunion hypothesis is a correct interpretation of the events leading to aberration production[13].

Different results have been obtained when MAL and TEM or EA and MAL were administered one following the other. In these circumstances the percentage of both iso'ocus breaks and chromatid translocations was not h'gher than additive in comparison with the control values from the treatments with MAL, TEM and EA alone, indicating absence of interaction of the chromatid breaks in exchange production. Since the period of maximal sensitivity of the interphase nucleus is in all probability identical for all three compounds used the time factor—restitution or rejoining of breaks induced by one agent before break induction by the other—cannot be used for an interpretation of the absence of interaction.

Considering the fact that there is only a restricted number of possible sites in the interphase nucleus where two chromosomes are so close together as to be able to produce an exchange[14] when two breaks occur in this area, an interpretation of the absence of interaction in our experiments may be seen in the different localization of aberrations induced by MAL[7] on the one hand and TEM[8,9] as well as EA[10] on the other. But since we found in fractionation experiments that breaks induced by TEM and EA seem to stay open at least for 8 h[15] whereas those induced by MAL are closed already after a time span of less than 3 h (unpublished results) the breakage of differential bonds by the agents may also play some part if the differential rejoining time really reflects a different nature of the bonds broken. It is not possible at present to point out the relative significance of these two factors which may be responsible for the absence of interaction between chromatid breaks induced by the combinations MAL–EA and MAL–TEM.

VIROLOGY

Interference Experiments relating to whether Tobacco Mosaic Virus and Cucumber Viruses 3 and 4 are Strains of the same Virus

THE problem of whether cucumber viruses 3 and 4 (CV3, CV4) and tobacco mosaic virus (TMV) are different viruses or strains of the same virus has been examined in detail by Knight[1]. On the basis of several criteria such as host-range, chemical composition, electron microscope morphology, etc., he concluded that they were different viruses. However, two criteria, serology and the ability to exhibit cross-protection, still support the idea that they are strains of the same virus. In regard to cross-protection, it was first found by Fulton[2] that prior infection of cucumber by CV3 and CV4 did not protect against subsequent TMV infection, but later Rochow[5] was able to demonstrate a high degree of protection. Apparently, the difference between Fulton's and Rochow's experiments is shown in the length of time the plant is allowed to sustain a CV3 and CV4 infection before it is challenged by a second inoculation with TMV.

Another method for assessing virus relationship has come from experiments which utilize mixed inocula[3]. This system of experimentation has shown that strains of TMV will markedly interfere with each other's lesion production when they are present in the same inoculum. The degree of interference is a function of the ratio of the two strains as well as the absolute concentration of the two strains in the mixed inoculum. In contrast, when the same system is used to test interference between tobacco necrosis virus and TMV, no interference is detected[4]. In addition to the mixed inoculum test, all other criteria indicate that the spherical tobacco necrosis virus is completely unrelated to the rod-shaped TMV. It was of interest, therefore, to investigate whether two rod-shaped viruses, CV4 and TMV, would display interference when analysed by the mixed inoculum system.

We have repeated the experiments of Fulton and Rochow and have confirmed their results. Cotyledons of 7–8 day old cucumber seedlings (*Cucumis sativus* L., var. Improved Long Green) were used. One cotyledon was inoculated with 1 mg of CV4/ml., and the opposite cotyledon was rubbed with phosphate buffer without virus. At different days after the inoculation, both cotyledons were re-inoculated with 0·5 μg of *U*1 (Common) TMV/ml. Four days after the TMV inoculation, the plants were placed in a dark room for 24 h, and then the starch lesions were developed and counted according to the method of Lindner *et al.*[5]. Since CV4 does not produce starch lesions on cucumber cotyledons, all lesions were scored as TMV lesions. The result of one such experiment is shown in Table 1. When the interval between CV4 and TMV inoculations was 6 days or less, virtually no interference with TMV lesion formation was observed. However, if the interval extended to 10 days, protection against TMV lesion formation was almost complete.

The possibility of interference between CV4 and TMV present in a mixed inoculum was also tested. A typical result was the following. One half of the cotyledons on 65 cucumber seedlings was inoculated with 0·5 μg TMV/ml. The other half was inoculated with a mixture that contained 0·5 μg TMV/ml., together with 250 μg CV4/ml. The total number of starch lesions that developed was 2,939 for TMV alone, and 3,001 for the mixture of TMV and CV4. Thus, no interference with TMV lesion formation by CV4 was detected in this or several other experiments. It may be recalled in this connexion that had 0·5 μg of one strain of TMV been present along with 250 μg/ml. of another strain, interference to the level of about 93–98 per cent would have occurred[3]. It also seemed possible that CV4 might be behaving like the *U*2 or *VM* strain of TMV on pinto bean leaves[3]. Under our environ-

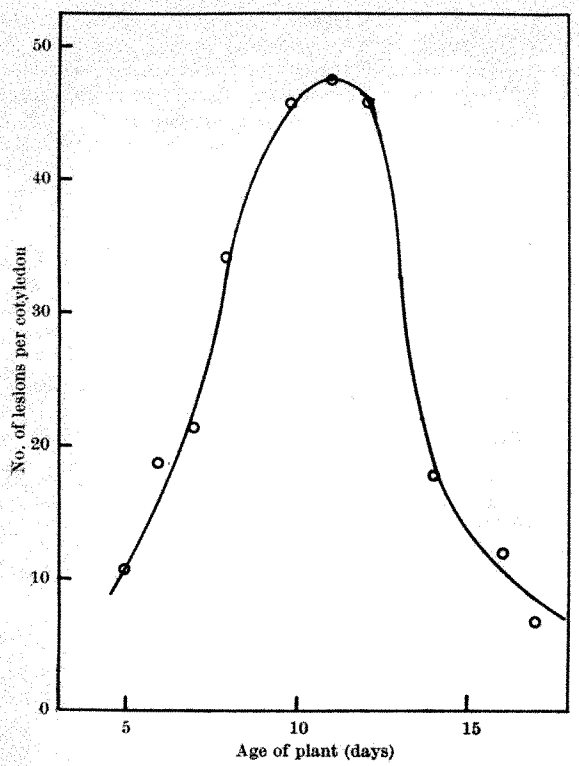

Fig. 1. Relationship between number of starch lesions produced by TMV and the age of cucumber cotyledons. Days indicate the time of inoculation after sowing the seeds. 0·5 μg TMV/ml. was used as an inoculum

mental conditions, *U2* and *VM* do not produce visible indications of having infected pinto bean leaves. However, the presence of *U2* or *VM* in a mixed inoculum with *U1* will strongly suppress lesion formation by *U1*. We therefore tested a mixed inocula containing *U1* and CV4 and found no suggestion of interference with *U1* lesion formation on pinto bean, scotia bean and *N. glutinosa*.

Thus, the additional criterion of absence by mixed inocula supports the view that CV4 and TMV are different viruses. But the question remains as to how to account for the cross-protection exhibited in Rochow's experiments. One possible explanation is that infection by CV4 alters the physiology of the host to a degree where a subsequent infection by TMV cannot proceed to the formation of starch lesions conspicuous enough to be detected by iodine staining. From Table 1, it is apparent that the number of starch lesions produced by the same concentration of TMV decreases as the age of the cotyledons increases. Additional experimental data plotted in Fig. 1 show this effect in greater detail where it was observed that cucumber cotyledons were maximally sensitive to TMV about 10 days after germination, and then rapidly lost their sensitivity. We have also observed that as sensitivity decreases with age, the TMV starch lesions also decline in size until they disappear entirely about 20 days after germination. Thus, the explanation we propose is that the presence of CV4 in a cucumber cotyledon merely accelerates the ageing process which normally operates to make the cotyledons resistant to TMV lesion formation. In this view, the cross-protection observed is not the direct result of two different viruses competing for the same virus synthesizing machinery within the same host cell. Rather, the presence of CV4 in some cells hastens the development of resistance in these and other cells that TMV may have invaded, but the resistance prevents the TMV infection from continuing to a visible stage. If sufficient time were allowed for the cotyledons to age, the resistance would have arisen in the absence of CV4.

Table 1. Effect of Previous CV4 Infection on the Number of TMV Starch Lesions

Age of seedlings at the time of TMV inoculation (days)	Interval between CV4 inoculation and TMV inoculation (days)	Total No. of lesions on 13 cotyledons not infected with CV4	Total No. of lesions on 13 cotyledons infected with CV4	Percentage protection of CV4 against TMV
11	4	651	700	0
13	6	456	371	18·7
17	10	127	8	93·7

We thank Dr. C. A. Knight, of the Virus Laboratory of the University of California, for supplying the strain of CV4. In this connexion, this strain did not prove to induce chlorotic and starch lesions on *N. tabacum* var Samsun and var. Xanthi-nc, and thus is different from the CV4 strain reported by Brcak *et al.*[7].

This work was supported in part by research grant E 536(C8), National Institutes of Health, U.S. Public Health Service, and contract AT(11–1)–34 project 8, U.S Atomic Energy Commission.

Transformation of Bovine Tissue Culture Cells by Bovine Papilloma Virus

Several viruses of the papovavirus group, namely polyoma, *SV*–40, and rabbit papilloma viruses, produce hereditable morphological alterations—'transformation'—of appropriate tissue culture cells[1]. We have found that another member of this group, the bovine papilloma virus produces cellular alterations and proliferation in certain bovine tissue culture cells after a very short latent period.

The changes in the cells occurred soonest and were most readily recognized in a semi-continuous diploid cell line of fœtal bovine conjunctiva (strain *DBC*). (All tissue cultures were obtained from Microbiological Associates, Inc. Bethesda, Maryland.) Tube cultures were held stationary at 36° C and maintained in medium N.C.T.C.–109 (ref. 2) with 10 per cent unheated agammaglobulinic calf serum ('Agamma Calf Serum', Hyland Laboratories, Los Angeles), penicillin, and streptomycin. Petri dish cultures were grown and maintained at 36° C in a humidified atmosphere of 5 per cent carbon dioxide in air; the medium was Eagle's basal medium with 10 per cent unheated fœtal bovine serum, and antibiotics. Freshly planted cultures of uninfected *DBC* cells consist of triangular, elongated cells of epithelioid or fibroblastic appearance; within several days, the cells form a continuous monolayer of polygonal cells resembling epithelium, with a few of the triangular cells at the periphery of the cell sheet. These control cultures remain unchanged with respect to cell type, and except for increasing granularity and non-specific degenerative changes, may survive for periods as long as 120 days. Cultures inoculated with 20 per cent extracts of three bovine papillomata (from cattle in Maryland, Wisconsin (supplied by Dr. Carl Olson, jun.), and Michigan (supplied by Dr. R. A. Tjalma, East Lansing)) consistently show distinct morphological changes within 3–10 days. The earliest change is the appearance of rather short, thin, spindle cells scattered over the cell sheet; in tube cultures, many long, thin, spindle cells appear at the periphery of the cell sheet. The majority of the epithelial cells then elongate, and

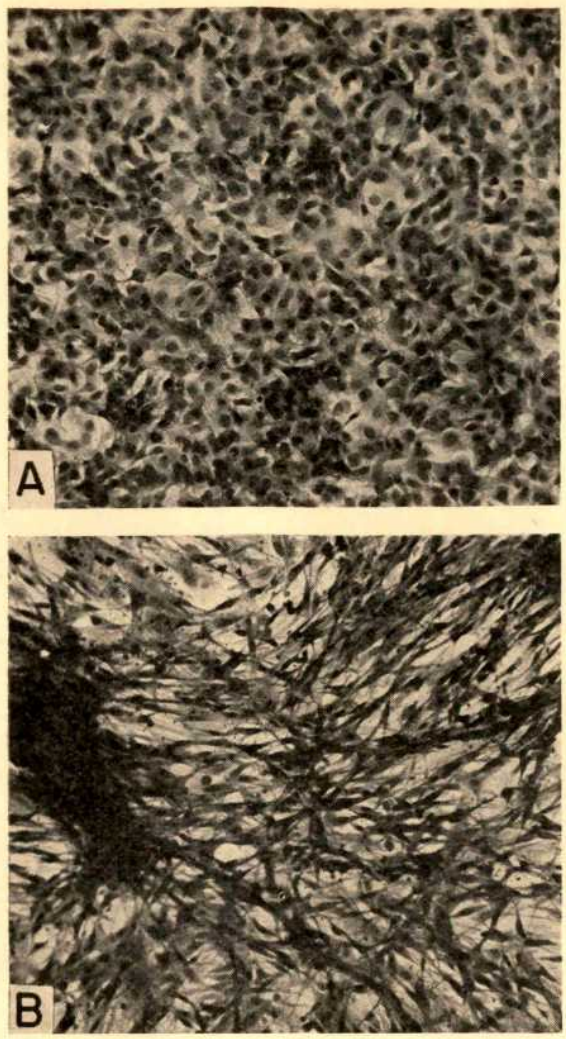

Fig. 1. Comparison of normal diploid bovine conjunctiva cells with transformed cells at third passage-level (hæmatoxylin and eosin, × *c.* 128). *A*, Control cells, primarily epithelial in morphology; *B*, transformed culture, consisting of spindle-shaped cells growing in disorganized pattern

within 10–14 days become long, thin, spindle cells, which grow in disorganized patterns, grow over the top of one another, and form a grossly thickened cell mass. In tube cultures, localized areas of more intensive proliferation may occur, which appear macroscopically as thick, whitish plaques. In cultures infected with a 10^{-2} dilution of a low potency extract, the changes were restricted to focal areas. Infected cultures acidify the medium more rapidly than do the controls.

The usefulness of the system was enhanced by the fact that within an experiment cultures inoculated with the same material showed almost identical changes.

When infected and control cultures are serially passaged by trypsinization, the morphological differences are maintained (Fig. 1), and the altered cells show a more rapid growth rate. One line of transformed cells is at present in the twenty-third serial passage.

The morphological transformation occurs most rapidly when freshly trypsinized *DBC* cells in suspension are exposed to virus. Cultures 6–11 days old are rinsed with Eagle's basal medium, and the cells dispersed with 0·25 per cent trypsin solution; an equal volume of growth medium is added, and the cells sedimented by centrifugation at 900 r.p.m. for 5 min. The cells are suspended in growth medium to give a concentration of 10^6 cells/ml. One volume of virus material is mixed with 10 volumes of cell suspension; after 1 h at room temperature, the mixture is diluted 10-fold, and 3·5 ml. added to Petri dishes (60 mm. diam. Falcon Plastics, Los Angeles). The cultures infected with undiluted extracts are clearly different from control cultures by the time the latter have formed confluent monolayers, at 2 or 3 days. Cultures infected with a 10^{-3} dilution of the most potent wart extract grew out as normal appearing epithelial cells, but by the fifth or sixth day underwent the characteristic sequence of change to abnormally growing spindle cells. In a comparative experiment, this wart extract, used undiluted, produced recognizable transformation within 3 days in cells infected in suspension, but required 10 days to induce definite changes when inoculated on to established cell sheets.

The ability of wart material to produce transformation was not destroyed by passing the extract through a bacteria-tight filter or by exposing the extract to 10 per cent chloroform for 10 min at 0° C. When a portion of this extract was fractionated by ultracentrifugation at 59,000*g* (avg.) for 2½ h, the washed pellet, resuspended to one-fifth the original volume in Eagle's basal medium, produced cellular alteration in 4 days, while the supernatant fluid produced changes only after 10–15 days. In the same test, the uncentrifuged extract produced transformation in 4 days.

Virus neutralization tests using the cellular transformation as the end-point gave clear-cut results. These tests were made by mixing serial dilutions of serum with a 10^{-1} dilution of wart extract; after 1 h at room temperature, the mixtures were added to cell suspensions as already described here. Paired sera from a heifer with naturally occurring papillomata showed a rising antibody titre; a 1 : 10 dilution of serum taken shortly after warts were detected did not affect the rate of transformation, while a 1 : 40 dilution of serum taken a month later completely prevented the changes. Serum (supplied by Dr. Olson) from a cow hyperimmunized with bovine papilloma suspension neutralized at a dilution of 1 : 5,120.

Other bovine tissue cultures have shown similar reactions to inoculation with the undiluted wart extracts. A diploid, epithelial-appearing, cell line of bovine kidney cells was infected in suspension; cellular elongation occurred in 4 days, but the early alterations were less easily discerned than in *DBC* cultures. Secondary cultures of fœtal bovine heart also responded, but with longer and more variable incubation periods. Primary bovine kidney cultures infected in suspension or as established cultures showed no alteration during observation periods of 34–108 days.

Preliminary evidence indicates that cultures of hamster embryo tissues show similar alteration to spindle cell morphology when inoculated with bovine wart extracts. No evidence of cytologic changes, altered growth pattern, or proliferation was observed after infection of primary, trypsin-dispersed, monolayer cultures of human embryonic skin-muscle, or kidneys of human embryos, rabbits and *C3H* mice, during observation periods of 38–53 days.

Attempts to induce transformation of *DBC* cultures with extracts of transformed *DBC* cells and of hamster fibrosarcomata induced by bovine papilloma virus[3] have been negative.

The alterations in cell morphology, growth-rate and pattern, and rate of acid-production suggest that the changes produced by the bovine wart extracts are comparable to the cultural transformation induced by other papovaviruses. Whether the altered bovine cells have malignant potentialities is not known; transformed *DBC* cells of the fifth serial tissue culture passage inoculated subcutaneously and into the conjunctiva of two calves 4 months of age have produced no evidence of tumour formation by the ninth week after injection.

That the agent responsible for the transformation is actually the bovine papilloma virus is indicated by the serological data; the chloroform resistance, filterability, and sedimentability of the agent; and by the occurrence

of positive results with wart extracts from cattle in three geographical areas.

Studies of wart viruses have been hampered by lack of convenient assay systems; none has been propagated in tissue culture, and no hæmagglutination has been detected. The bovine wart virus produces lesions in cows, horses[4], and hamsters[3]; but these systems are either cumbersome or insensitive. Since transformation was induced by virus dilutions as high as 10^{-3}, the highest dilution tested, it is possible that the system described here may provide a relatively sensitive assay for virus. However, its sensitivity relative to inoculation of cows or horses remains to be determined. The *DBC* cells do not appear to provide a method for propagating the virus, and in this respect the cell-virus relationship resembles some of the transformation systems with other papovaviruses[1].

The high percentage of *DBC* cells that are transformed by the bovine wart viruses suggests that this may be a particularly useful model system for studies of cellular transformation by viruses.

PSYCHOLOGY

Use of 3-Dimensional Shapes for Investigation of Learning Sets in the Rat

In a series of experiments, Harlow[1] and other investigators have studied learning-sets in a number of species. Their evidence demonstrates that the ability to form learning sets is related both to the phylogenetic 'level' of a species and to the individual animal's ontogenetic development. When trying to establish learning sets in such an animal as the rat, the difficulty has been that the learning of individual problems has taken so long that it was not possible to present sufficient problems to examine this phenomenon of learning to learn.

In an effort to achieve faster learning, the following apparatus was constructed using 3-dimensional shapes as discrimination stimuli. In this situation a rat not only sees an object but also touches and moves it. The procedure is sufficiently close to that of Harlow's work with primates to allow a comparison of learning-set formation with other species.

The animal was placed in a wooden box 12 in. × 10 in. At one end were two apertures 6 in. across and 4 in. high. The floor of each aperture was wooden and raised towards the back wall at an angle of 10°. In the centre of the floor of each aperture was a food-well ¼ in. × ½ in. over which a wooden 3-dimensional shape was placed. There were two screens dividing the box from the apertures. A transparent inspection screen allowed the animals to see both shapes but prevented any approach to them until it was raised; a second opaque screen prevented animals from observing the change-over of shapes and from correcting their responses. The inside of the apparatus, with the exception of the white wooden shapes, was painted black.

Twelve male black hooded Norway rats were used; seven were 4 months and five were 11 months old at the beginning of the experiment. An animal was first trained to eat pieces of spaghetti from the food-wells and then learned to 'nose' off the shapes to find food beneath. In the experiment itself a rat, after being deprived of food for 20 h, was placed in the box with both screens 'down'. The stimulus shapes were placed in position, the 'correct' one was baited and the opaque screen was then raised for an inspection period of 5 sec, after which the inspection screen was raised so that the animal could respond. If the animal made a correct response, time was allowed for it to take the food and eat; if incorrect, then the screens were immediately lowered. An error was recorded when the animal entered the wrong aperture, and a correct response when the shape over the baited well was pushed away. The inter-trial interval was approximately 10 sec.

Each animal was given 210 trials on problem 1 (Fig. 1), and each achieved more than 75 per cent correct responses on the trials for the last day. Problems 2–5 were then presented for 100 trials at 25 a day. Once again all animals reached the criterion of 75 per cent correct responses. At this point it seemed that animals might reach this criterion in fewer than 100 trials, so problems 6–18 were run at 25 trials a day and changed immediately after passing the criterion. Most animals did in fact reach criterion on all problems in 50 trials. In order to present more problems to each animal, problems 19–58 were given at 2 a day and 10 trials per problem.

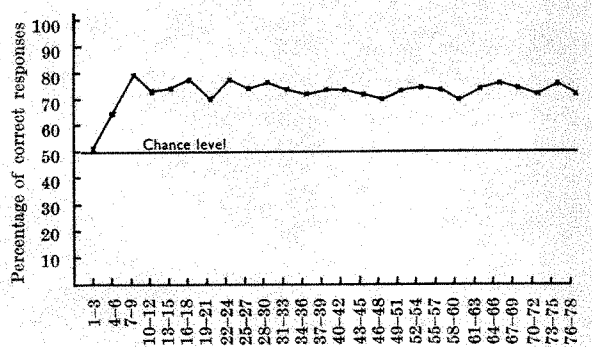

Fig. 1. No. of correct responses for first ten trials on problems 1–78

The animals again scored above chance; but towards the end of the problems scores were fluctuating and the latency of responses was increasing. Since further improvements with this rapid changing of problems seemed unlikely, the final problems, 59–78, were presented for 25 trials each at 1 problem a day. There was no marked change in performance for these last 20 problems though the scoring was again well above chance.

The scores for the first 10 trials for all problems are presented in Fig. 1. These animals had clearly learned how to react to this rapid change of pairs of stimuli and achieved scores which indicate some mastery of the task. By using three-dimensional shapes it was possible for these rats to learn 78 discrimination problems in a period of less than 3 months. This was considerably faster than with experiments using two-dimensional shapes, and gives some hopes that with this type of apparatus it should be possible to present a sufficient number of problems to these animals to make phylogenetic comparisons. So far, on the evidence of the present results, the rat learned quicker than with two-dimensional shapes, but, as a species, it was not so rapid as other animals higher in the phylogenetic scale.

FORTHCOMING EVENTS

Monday, September 9—Friday, September 13

INSTITUTE OF PHYSICS and the PHYSICAL SOCIETY (at Imperial College of Science and Technology, London, S.W.7)—Conference on "The Liquid State".

Tuesday, September 10

SOCIETY FOR ANALYTICAL CHEMISTRY, ATOMIC ABSORPTION SPECTROSCOPY DISCUSSION PANEL of the PHYSICAL METHODS GROUP (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6.40 p.m. —Discussion Meeting initiated by an introductory paper by Dr. J. B. Willis (C.S.I.R.O., Australia).

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

SCIENTIFIC OFFICER/SENIOR SCIENTIFIC OFFICER (with a first- or second-class honours degree in mathematics, and an interest in, and knowledge of, statistical methods) AT THE ROAD RESEARCH LABORATORY, D.S.I.R., Harmondsworth, Middx, to undertake research in the field of road transport in tropical and sub-tropical countries—(the work involves regular visits overseas)—The Director, Road Research Laboratory, D.S.I.R., Harmondsworth, Middx (September 12).

RESEARCH ASSISTANTS (at least two, with a first degree in physiology, biochemistry, chemistry, or zoology) IN THE DEPARTMENT OF PHYSIOLOGY AND BIOCHEMISTRY, to join research groups studying the endocrinology of hypothermia, biochemical aspects of food processing, or invertebrate neurophysiology—The Secretary and Registrar, The University, Southampton (September 13).

CHIEF TECHNICIAN (with qualifications in histology)—Head, Department of Physiology and Pharmacology, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (September 14).

D.S.I.R. RESEARCH ASSISTANT (with training in zoology or physiology or psychology) IN THE DEPARTMENT OF ZOOLOGY, to assist in research in the neurology and behaviour of birds—The Registrar, The University, Liverpool, quoting Ref. CV/399/N (September 14).

LECTURER (preferably with an interest in control systems, data processing or communication theory and the application of electronic circuits to these or related fields) IN ELECTRICAL ENGINEERING—The Registrar, University College of Swansea, Singleton Park, Swansea, South Wales (September 14).

SENIOR BIOCHEMIST (with at least five years previous experience of hospital work) IN THE DEPARTMENT OF CHEMICAL PATHOLOGY in the Group Laboratory, for duties principally in laboratory supervision—The Group Secretary, Epsom Group Hospital Management Committee, Epsom District Hospital, Epsom, Surrey (September 14).

LECTURER IN BIOCHEMISTRY (Veterinary Biochemistry)—The Secretary of University Court, The University, Glasgow (September 15).

TECHNICIAN or ASSISTANT TECHNICIAN (preferably with experience in a microbiological laboratory) IN THE BOTANY DEPARTMENT, University of Canterbury, New Zealand—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, September 18).

SENIOR EXPERIMENTAL OFFICER (with a degree or equivalent qualification in physics and engineering, several years experience in a research laboratory, and preferably a thorough practical knowledge of the design and operation of electronic equipment) IN THE DEPARTMENT OF NUCLEAR ENGINEERING, University of Manchester, and based at the University Reactor Centre at Risley, near Warrington (operated jointly by the Universities of Liverpool and Manchester), to be responsible, under the Research Manager, for planning and safety evaluation of work on the reactor, and also for the design and manufacture of equipment used in conjunction with it—The Registrar, The University, Manchester 13 (September 20).

LECTURER IN THE DEPARTMENT OF EDUCATION—The Secretary, The University, Aberdeen (September 21).

RESEARCH ASSISTANT (honours graduate in botany or biochemistry, and interested in working towards a higher degree) IN THE DEPARTMENT OF BOTANY—Prof. Carr, Department of Botany, David Keir Building, The Queen's University of Belfast, Stranmillis Road, Belfast 9, Northern Ireland (September 21).

SENIOR DEMONSTRATOR (honours graduate in botany or biochemistry) IN THE DEPARTMENT OF BOTANY—Prof. Carr, Department of Botany, David Keir Building, The Queen's University of Belfast, Stranmillis Road, Belfast 9, Northern Ireland (September 21).

SENIOR LECTURER IN CHEMICAL PATHOLOGY—The Registrar, The University, Sheffield (September 21).

SENIOR RESEARCH FELLOW (with post-doctoral experience using particle counting techniques) and a RESEARCH ASSISTANT IN THE DEPARTMENT OF PHYSICS, to join a group developing and testing satellite equipment for cosmic ray recording—Dr. P. L. Marsden, The University, Leeds (September 23).

SENIOR LECTURER and a LECTURER IN MATHEMATICS at the University College of Townsville, University of Queensland, Australia—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, September 27).

RESEARCH OFFICER (Biochemist) (with a Ph.D. degree, or postgraduate research experience of equivalent standard and duration supported by satisfactory evidence of research ability, and preferably training and experience in mammalian biochemical research) IN THE McMASTER ANIMAL HEALTH LABORATORY, Division of Animal Health, Commonwealth Scientific and Industrial Research Organization, Sydney, to undertake research in some aspects of chemical pathology, particularly in relation to the effects of parasitism—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 202/214 (September 28).

ASSISTANT LECTURER (preferably with special training in either mathematics or psycho-pharmacology) IN EXPERIMENTAL PSYCHOLOGY—The Registrar, The University, Manchester 13 (September 30).

ASSISTANT LECTURER (with a good honours degree in metallurgy or chemistry) IN CHEMICAL METALLURGY in the Department of Metallurgy in the Faculty of Science—The Registrar, The University, Manchester 13 (September 30).

ASSISTANT LIBRARIAN (graduate with a professional qualification) at Fourah Bay College, The University College of Sierra Leone—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (September 30).

CHAIR OF BIOCHEMISTRY at Victoria University of Wellington, New Zealand—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, September 30).

D.S.I.R. RESEARCH FELLOW (with a Ph.D. or equivalent postgraduate experience in experimental geophysics, and preferably experience in the maintenance or development of electronic equipment) IN SEISMOLOGY IN THE DEPARTMENT OF ASTRONOMY, to undertake field and laboratory studies of seismic waves and to relate their observations to earth structure and tectonics—Secretary to the University, University of Edinburgh, Old College, South Bridge, Edinburgh (September 30).

LECTURER IN BIOCHEMISTRY IN THE DEPARTMENT OF CHEMISTRY in the Faculty of Science—The Registrar, The University, Manchester 13 (September 30).

LECTURERS (2) IN RADIO-ASTRONOMY IN THE DEPARTMENT OF PHYSICS of the Faculty of Science, to pursue research at the Nuffield Radio-astronomy Laboratories, Jodrell Bank—The Registrar, The University, Manchester 13 (September 30).

READER (with appropriate academic qualifications and teaching experience) IN PHILOSOPHY at the University of Hong Kong—The Secretary, The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, September 30).

SCIENTIFIC OFFICER or SENIOR SCIENTIFIC OFFICER (with a first- or second-class honours degree in biochemistry or a closely related subject, and preferably experience of the chemistry of carbohydrates or of the use of radioactive carbon) IN THE DEPARTMENT OF BIOCHEMISTRY, for work on the nature and origin of the carbohydrate fraction of soil organic matter—The Secretary, The Macaulay Institute for Soil Research, Craigiebuckler, Aberdeen (September 30).

CHEMIST (Corrosion) (preferably with an honours degree and some research experience) in the Dominion Laboratory, Department of Scientific and Industrial Research, Lower Hutt, New Zealand, to work with a small team undertaking investigational work on corrosion of metals and related problems such as corrosion and diffusion of hydrogen in metals exposed to geothermal steam, sulphide stress cracking, delayed hydrogen fracture, mechanisms of corrosion in water supply systems, corrosion and stress corrosion in aircraft constructional materials—The High Commissioner for New Zealand, New Zealand House, Haymarket, London, S.W.1, quoting Ref. B.13/18/17/2331 (October 2).

CHAIR OF SURGERY at the University of Hong Kong—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, October 5).

LECTURER/ASSISTANT LECTURER (preferably with special interests in the fields of plant anatomy and morphology, angiosperm taxonomy or phycology) IN BOTANY at the University of Hong Kong—The Secretary, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, October 5).

CHAIR OF BOTANY; and CHAIR OF EDUCATION at the University of Basutoland, Bechuanaland Protectorate and Swaziland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (October 10).

CHAIR OF PURE MATHEMATICS—The Registrar, The University, Manchester 13 (October 12).

UNIVERSITY LECTURER IN BIOCHEMISTRY, for duties which will include teaching and research—T. D. Kellaway, Secretary of the Appointments Committee, Department of Pathology, The University, Tennis Court Road, Cambridge (October 14).

LECTURER or ASSISTANT LECTURER IN GEOLOGY at the University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (October 20).

ASSISTANT (with experience in technical information work, and preferably a qualification in science or engineering) TO THE EDITOR OF *Fuel Abstracts and Current Titles*, to be responsible for the subject indexing of this monthly journal—The Secretary, The Institute of Fuel, 18 Devonshire Street, London, W.1.

ASSOCIATE PROFESSOR (preferably working on the integrative aspects of mammalian physiology, especially in the neuroendocrine, gastro-intestinal or cardiovascular fields) IN PHYSIOLOGY—Prof. J. W. Pearce, University of Alberta, Edmonton, Alberta, Canada.

CHEMIST (Veterinary) (under 45 years of age, with an honours degree in chemistry, preferably with some veterinary/agricultural or medical experience, and experience in biochemistry) IN THE DEPARTMENT OF AGRICULTURE, Tanganyika, to supervise the Chemical Section of the Veterinary Research Laboratory, including frequent safaris for experiments in the field—The Director of Recruitment, Department of Technical Co-operation, Eland House, Stag Place, Victoria, London, S.W.1, quoting Ref. RC/Cl. 213/145/05.

FOREST TREE BREEDER (not over 40 years of age, with an honours degree in forestry, or equivalent, postgraduate ezperience in forest tree breeding, and preferably with a Master's degree and experience in silviculture or wood anatomy) IN THE EAST AFRICAN AGRICULTURAL AND FORESTRY RESEARCH ORGANIZATION, to undertake an approved programme of tree breeding and selection, in which the principal species concerned will be pines (particularly *P. radiata* and *P. patula*) and cypruses of the *C. lusitanica* group—The Director of Recruitment, Department of Technical Co-operation, Eland House, Stag Place, Victoria, London, S.W.1, quoting Ref. C1/RC. 264/348/08.

LECTURER (medical or non-medical) IN BACTERIOLOGY—The Secretary, The Welsh National School of Medicine (University of Wales), 34 Newport Road, Cardiff.

LECTURER (with at least a good honours degree in chemistry, some teaching and research or industrial experience, and an active interest in research) IN INORGANIC CHEMISTRY, to teach to Grad. R.I.C., B.Sc. General and H.N.C. standards—The Principal, South-East Essex Technical College and School of Art, Longbridge Road, Dagenham, Essex.

ORGANIC- or BIOCHEMIST (young graduate), to join a team studying the relationship between wheat variety and growth conditions and lipid composition—The Secretary, British Baking Industries Research Association, Chorleywood, Rickmansworth, Herts.

RESEARCH ASSISTANT for wind tunnel research in the field of industrial aerodynamics—Head, Aeronautics Department, Imperial College of Science and Technology, London, S.W.7.

RESEARCH ASSISTANT IN THE DEPARTMENT OF CHEMISTRY, to investigate the surface properties of clean metals and semiconductors and their subsequent reactions with gases—Dr. M. W. Roberts, Department of Chemistry, The Queen's University, Belfast, Northern Ireland.

RESEARCH ASSISTANT (with a knowledge of mathematics up to at least first-year university honours standard, and preferably experience in statistical and bibliographical work) IN THE RESEARCH TECHNIQUES DIVISION, to assist with the preparation of a bibliography of statistical literature—Prof. J. Durbin, The London School of Economics and Political Science, Houghton Street, London, W.C.2.

RESEARCH OFFICER (national of, and permanently resident in, Great Britain or the Republic of Ireland, medical qualifications registrable in the United Kingdom or an honours degree in zoology or allied subject, an aptitude for research, and preferably research experience in protozoology, bacteriology or virology) AT THE LABORATORIES OF THE EAST AFRICAN TRYPANOSOMIASIS RESEARCH ORGANIZATION, to undertake research on human trypanosomiasis and its wild animal reservoirs, mainly from the protozoological and immunological aspects, in association with field studies by other officers on the epidemiology of the disease—The Director of Recruitment, Department of Technical Co-operation, Eland House, Stag Place, Victoria, London, S.W.1, quoting Ref. RC.264/309/02.

SENIOR TECHNICIAN (with experience in a similar post) IN THE DEPARTMENT OF GEOLOGY—The Professor of Geology, The University, Leicester.

SUPERINTENDENT (with a degree in biological science or equivalent qualification, for example, F.A.T.A., and experience in some branch of animal work), to take charge of the Physiology Department's goat and small animal house—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, quoting Ref. 63/2.

TECHNICAL OFFICER (with a degree in agriculture or agricultural botany, or a National Diploma) IN THE ROOT AND FODDER CROPS SECTION OF THE TRIALS BRANCH—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge.

TECHNICIAN FOR A.R.C. UNIT OF FLOWER CROP PHYSIOLOGY at Shinfield, to maintain controlled environment equipment and develop research apparatus—The Assistant Bursar, The University, Reading.

CENTRALIZING BRITAIN'S DEFENCE ORGANIZATION

THE White Paper on *Central Organization for Defence** demands some attention from scientists and perhaps also a close scrutiny from the Parliamentary and Scientific Committee. It details proposals for a reorganization which were foreshadowed in the speech of the Minister of Defence, then Mr. P. Thorneycroft, when moving the approval in the House of Commons of the *Statement on Defence 1963*† on March 4. In that speech, Mr. Thorneycroft expressed doubts as to whether the Ministry of Defence possessed sufficient effective power to make the defence budget a real synthesis of defence problems and whether, when resources were under pressure, the interests of individual Services did not prevent the formulation of a real central policy. More significant still for the scientist and technologist, he questioned whether research and development could be really effectively devised and controlled, and admitted that this was one of the most difficult problems of all.

How important this last matter has become is sufficiently illustrated by the figures given in the *Statement on Defence*. For 1963–64 there is shown in the Defence statistics a separate item of £5·4 million for the cost of defence research undertaken and financed by the Atomic Energy Authority. This item is included in the total net estimate of £769·8 million for research and development in a net budget of £1,837·7 million, although research and development are not separately distinguished. For the Admiralty the net figure is £235·1 million; for the War Office, £93·4 million; for the Air Ministry, £244 million; and for the Ministry of Aviation, £530·95 million gross or £191·87 million net.

The memoranda accompanying the separate estimates of the Navy, Army and Air Force, which are included with the *Statement*, all emphasize the importance of continuing research and development. The memorandum accompanying the Navy Estimates, for example, besides referring to the value of the International Indian Ocean Expedition and of the National Institute of Oceanography —which are financed partly from the Admiralty—stresses the importance of the shore-based prototype nuclear submarine installation at Dounreay. This is regarded as essential for future development of submarine reactors and training personnel; note is made of the considerable effort being devoted to ship-borne automatic data-processing and display systems for the overall defence of the fleet. The memorandum on the Army Estimates refers to the new system of radio communications known as the Clobart plan now under design study. This aims at rationalizing and integrating the new generation of radio equipment, taking account of improved engineering techniques, and using computer techniques which would enable subscribers in the field to achieve rapid, automatic inter-connexion wherever they are. This is, of course, apart from the effort which has gone into the development of new anti-tank weapons, the General Purpose Machine Gun and a new battle tank. Long-term projects include research into more advanced armoured fighting vehicles, the development of high strength and temperature-resistant metals, and work on improved ammunition fuses, engines and bridging.

Although the memorandum on the Air Estimates makes no specific reference to research and development, the vital importance of such work for the development of the new aircraft required is just as apparent as it is for the Navy and the Army. Nevertheless, for all Mr. Thorneycroft's observations in the House of Commons, the *Statement on Defence 1963* is no more than a compilation of the Estimates from the three Service Ministries and the accompanying separate memoranda. There is no covering statement from the Ministry of Defence and the shortcomings of the existing organization, and the virtual bankruptcy of the arrangements made in 1958 as regards co-ordinated policy on research and development or on any other aspect of defence could scarcely have been made plainer.

Mr. Thorneycroft, in announcing on March 4 that the Government had agreed that there should be one unified Ministry of Defence on a Service basis, with the one Department of Defence responsible for advising the Government on defence policy, and housed in one building, rejected the idea of an amalgamation of the Services. However, neither then nor in the White Paper now issued can reference be found to the undoubted advantages which some measure of joint training for junior officers would offer, particularly in its ultimate effect on integration and co-operation. He pointed out, however, that most of the research and development work of the Ministry of Aviation was done for the Ministry of Defence and the Service Ministries on an agency basis, and he thought that it was desirable to keep military and civil aviation research and development together. No final decision had then been taken as to whether the Ministry of Defence should take over all such research and development and carry out the rather smaller civil part on an agency basis for another Ministry.

The fact that research and development could not well be separated from production was against such a step. However, the question was not examined further either by Mr. Thorneycroft or in the subsequent debate, and this solution has now been rejected. Nor, apart from Lord Robertson of Oakridge's reference, was the question of research organization raised in the House of Lords debate on March 14. According to the White Paper, the Ministry of Aviation will retain its wide responsibilities for civil as well as for military research and development as an independent department responsible for executing programmes of defence research, development and production formulated and approved by the Secretary of State for Defence. The Minister of Aviation will not be a member of the new Defence Council which replaces the Defence Board, but will attend the Defence Council whenever meetings affecting his Department are under consideration. The Ministry of Aviation will be fully associated with the new arrangements for formulating operational requirements, for controlling defence research and development, and for evaluating weapons systems. The Ministry of Defence will in future be represented on the main departmental committees of the Ministry of

* *Central Organization for Defence*. Pp. iii+14. (Cmnd. 2097.) (London: H.M.S.O., 1963.) 1*s*. 6*d*. net.

† *Statement on Defence 1963*, including Memoranda to Accompany the Navy, Army and Air Estimates, 1963–64. Pp. 87+24 plates. (Cmnd. 1936.) (London: H.M.S.O., 1963.) 8*s*. 6*d*. net.

Aviation responsible for managing defence research, development and production programmes.

The omission of the Ministry of Aviation from the formal structure of the new organization is to be further balanced by ensuring the freest possible communication at all levels between the Ministry of Defence and the headquarters and establishments of the Ministry of Aviation. Scientists in the latter Ministry will be freely available to serve on panels in the Ministry of Defence and free interchange is also proposed for senior staff. This will be particularly so for defence scientists, of the administrative and other Civil Service classes in the two Ministries. To assist close consultation, the Minister of Aviation and those senior officials who are mainly or exclusively concerned with defence projects will be accommodated in the same building as the staffs of the Ministry of Defence who are responsible for policy. Arrangements are to be made for the regular and easy interchange of staff between the two Ministries, particularly in the scientific field.

These measures, together with new and improved procedures for controlling the research and development programme, are expected to result in closer monitoring of the progress of individual major projects, so that technical and cost factors which seem likely to cause unforeseen difficulties will be identified with greater speed and certainty, enabling decisions to overcome such difficulties to be taken promptly. In this, however, the decisive factor is likely to be the Defence Scientific Staff, now to be established. Before discussing this, however, the broad structure of the new arrangements should be described.

They comprise absorption in the new Ministry of Defence of the present Ministry, the Admiralty, War Office, and Air Ministry—authority and responsibility being vested in a single Secretary of State for Defence with complete control both of defence policy and the administrative organization. However, the Services will preserve their separate identities and the Chief of the Defence Staff and the three Chiefs of Staff will retain their right of access to the Prime Minister. The new Defence Council will comprise, besides the Secretary of State for Defence, the three Ministers of State for the Navy, the Army and the Air Force, the Chief of the Defence Staff, the three Chiefs of Staff, the Chief Scientific Adviser to the Secretary of State for Defence and the Permanent Under-Secretary of State for Defence, and will deal mainly with major defence policy.

The Chief Scientific Adviser's work covers all aspects of defence which are affected by scientific advance, and, to enable him to play his full part in the formulation and control of the defence research and development programme, several changes are being made. First, the establishment of the Defence Operational Requirements Staff, under an assistant chief of the Defence Staff to review long-term requirements, who will sponsor long-term studies on future concepts of war, and examine and harmonize all major new weapon requirements. This should improve the arrangements for formulating military requirements, and it is proposed that whenever the problems are of a Defence and not a single Service character, the scientific staffs of the present Ministry of Defence and the present Service Departments will work together under the Chief Scientific Adviser as the Defence Scientific Staff. Next, the present Defence Research Policy Committee will be replaced by two new Committees, of both of which the Chief Scientific Adviser will be chairman. These Committees will work closely with the Defence Operational Requirements Staff and the Defence Secretariat, but no reference is made to relations with the Advisory Council for Scientific Policy, and it would seem improbable that the chairman of that Council can, in future, also be chairman either of the new Defence Research Committee or of the Weapons Development Committee.

The Defence Research Committee will oversee all military research which does not directly support approved weapons and equipment projects. It will advise the Secretary of State and the Chiefs of Staff on all scientific and technical matters which may affect defence research policy, and will keep the defence research programme under review so as to ensure that it is appropriate to defence needs and is matched by the resources available. In particular, it will be responsible for bringing to notice, in good time, scientific developments which may be of military interest. Its membership will be mainly scientific and will include independent scientists.

Closely linked to this Committee by a substantial degree of common membership will be a new Weapons Development Committee. This Committee will draw to a larger extent on military and administrative staffs and will advise the Secretary of State and Chiefs of Staff on what major developments should be included in the development programme. It will keep that programme under review so as to ensure that it is properly matched to available resources, current defence policy and operational requirements agreed in the light of what is technically feasible, and it will be responsible for the prompt detection of any difficulties which may rise in the execution of the programme. The Ministry of Aviation will be represented on both these Committees, and a third committee, consisting of the directors of operational research of the three Services, with a member of the Chief Scientific Adviser's staff as chairman, will co-ordinate operational research activities.

The staff under the Chief Scientific Adviser will be increased primarily to provide adequate service for these Committees, to undertake and develop techniques for the study and evaluation of weapons systems, undertake cost-effectiveness studies where appropriate and to investigate longer-term problems of a scientific nature which have a bearing on defence policy. The increase is also needed in order to develop close association at all levels between the Defence Scientific Staff and the Defence Staff and Defence Secretariat. The normal method of working contemplated under the direction of the Chief Scientific Adviser is to form *ad hoc* panels, or working groups, to deal with specific problems, drawing on appropriate specialists from the military, scientific and civil administrative staffs of the Ministry, the Ministry of Aviation and the Services, and on outside advisers.

Co-ordination is the responsibility of the Permanent Under-Secretary of State, who will be assisted by four Second Permanent Under-Secretaries of State, one of whom will be specifically responsible for identifying fields in which administration might with advantage be placed on a Defence rather than a single Service basis and for recommending any appropriate changes in Department organization for this purpose. It is fully recognized, however, that any long-term financial planning and control of the defence programme and allocation of resources, which will be a primary responsibility of the Permanent Under-Secretary himself, must take into account political, military, scientific, technical, financial and economic

factors. Constant collaboration between military, scientific and civil administrative staffs will be required, besides a sound appreciation of each other's problems and a common effort to improve planning and control techniques. The co-ordination of the views of the military, scientific and civil administrative staffs is a further responsibility of the Permanent Under-Secretary. There is also a reference to the importance of effective management so as to safeguard the career interests and welfare of all staff, so far as possible, on a defence basis. It is recognized that it is important that civil administrative staff in the Defence Secretariat, who are specially concerned with a particular Service, together with the scientific staffs of the Services, should continue to make a major contribution to management.

It could be urged that the reorganization proposed, which leaves the three Services intact, does not go far enough, and admittedly the proposals fall far short of what has already been put into practice in the United States and advocated in Britain by Lord Montgomery. Nevertheless, it leaves the way open for further changes and it seems improbable that inter-service training of officers can long be delayed. The system may well work, though that will obviously depend, as in fact the White Paper admits specifically in respect of defence research, on the men it can attract and the judgment they can bring to bear on problems which are seldom amenable to straightforward analysis and accounting and which involve, in varying degrees, military, scientific, technical, financial and economic content.

On the scientific side the changes are indeed considerable. Bearing in mind the criticism of the Select Committee on Estimates, it may reasonably be doubted whether with the establishment of a scientific staff in the Defence Ministry, the retention of independent scientific research staffs in the separate Service Departments is justified. However, the spirit of the White Paper is encouraging and goes some way to meet criticisms which have been advanced and hesitations on the part of scientists to commit themselves to research on defence problems. The decision regarding the Ministry of Aviation is a matter of opinion, but the proposals have been at pains to meet possible objections and it would seem that they would also provide for any appropriate co-operation with such bodies as the Institute of Strategic Studies.

Where they seem most open to criticism on the scientific side is in relation to scientific and technological research generally. The absence of any link with the Advisory Council for Scientific Policy has already been noted, and similarly, when the relation of the new Ministry to the Cabinet is considered, there is no reference to the Minister for Science, in spite, too, of his formal responsibility for the Atomic Energy Authority. Some formal link with the civil research organization seems desirable, if not essential, if the Defence Research Committee is to discharge one of its specific responsibilities efficiently, and the omission is the more pointed in view of the elaborate arrangements regarding the Ministry of Aviation. Nor is the contact of importance in one direction only. Any considerable disarmament effort could make such a link imperative if the full possibilities in the civil field of any advances in defence research are to be realized. This may become the more important as the Ministry of Defence acquires effective control over the Services.

It is in such respects as these that the White Paper does not seem to look sufficiently to the future. It is at pains to remove some of the obstacles to co-operation which have existed in the past and some of the factors which have discouraged able minds from participating in defence research and development. Even as yet, however, the magnitude of the problem of communication has not been fully grasped. There is, none the less, a framework which should be welcomed and which, if wisely and imaginatively used, could eliminate mistakes of the magnitude which have marred Britain's defence effort in the past. Moreover, it could also contribute to the more effective use of Britain's resources, whether of manpower or materials, alike in defence itself or in the run-down with all the economic and technical problems which will be posed if disarmament on any real scale once becomes feasible. Last, but not least, what is here set forth offers ample scope for taking defence policy and expenditure out of the arena of party politics—an essential condition alike for achieving a really effective defence policy and securing the whole-hearted participation of the scientist.

BACCHANALIAN ADDICTION

Alcoholic Addiction

A Psycho-social Approach to Abnormal Drinking. By Howard Jones. Pp. x+209. (London: Tavistock Publications, 1963.) 30*s*.

THIS book, giving in the main a very stimulating account of research carried out in Canada in a residential treatment unit and in a prison, is concerned with "Anglo-Saxon alcoholism". It claims that the "size of [the] alcohol problem and extent of its consequences for society and individual more than justify research into its causes and treatment". How far is this statement true for England? On p. 7 the book shows a table compiled by a Canadian authority which, like a similar table published previously by the World Health Organization, ranks England and Wales last but one among twelve listed countries with regard to the estimated prevalence of alcoholism. But, even so, the author quotes a Ministry of Health source that this estimate for England and Wales represents a proportion more than forty times as great as the proportion of ascertained mental defectives in the whole population of the country in the same year; and in England and Wales in the decade 1951/1961 nearly one in 10 prison receptions consisted of men or women sentenced for inebriate offences (excluding offences such as assault and vagrancy, which may often result from drinking). There has been in Britain recently a spectacular rise in convictions for drunkenness—the author quotes a figure of a 250 per cent increase between 1946 and 1960, and the rise has been continuing since. There are other indirect signs that alcoholism in Britain may well be on the increase. It is clear that research into alcohol problems—such as described by Dr. Jones—is a vital necessity also with regard to conditions in Britain, and his results and conclusions deserve the greatest interest.

The author, a sociologist, uses a social criterion to define alcoholism: ". . . a chronic behavioural disorder manifested by repeated drinking of alcoholic beverages . . . to an extent that interferes with the drinker's health or his social or economic functioning". He has adapted this definition from one proposed by Keller in 1958, but it also resembles that given by the World Health Organization in 1952. But unlike the World Health Organization (and unlike Jellinek, who is frequently referred to in this volume) he does not use medical criteria ('loss of control' and 'inability to abstain') to define 'alcohol addiction', but the social criterion—the 'addict' continues to drink excessively even though, as a result, his social life and his happiness are being gradually

destroyed. Dr. Jones disagrees with Jellinek's criticism of an entirely psycho-social explanation of the nature of alcohol 'addiction'. According to Jellinek, physical withdrawal symptoms are the basis of alcohol 'addiction'; against that, Dr. Jones argues that the addict will resume drinking again even after being 'dried out' thoroughly: "this must be one manifestation of his 'addiction', in any normal usage of this word"; and this phenomenon is "hardly consistent" with a physiological explanation, but "readily explainable in psycho-social terms". Dr. Jones also states that there is, so far, no evidence to support Jellinek's hypothesis of a virtually irreversible metabolic abnormality to explain why the alcoholic sets off on a new bout once he resumes drinking. He rather favours psychosomatic explanations: physical withdrawal symptoms may be psychological in origin. "The persistence of unsatisfied psychological needs in the alcoholic may also have its counterpart in the physical experience of the withdrawal phase, both being directed towards the same aim of continued drinking. The long-lived physical dependence . . . may then be seen as a translation into bodily terms of such a persisting psychological dependence".

Discussing the ætiology of alcoholism, the author remarks that physical explanations of disease are usually preferred to psychological ones, and he quotes in this connexion the concept of 'physical allergy' so popular with 'Alcoholics Anonymous' (although in fairness one has to add that the latter couple it with the additional one of a 'mental obsession'). Striking cultural variations in the prevalence of alcoholism among different communities are "perhaps the most telling argument against exclusively physiological causation". In this part of his discussion, the author largely follows Jellinek's hypotheses. Excessive drinking may stem from the life of the addict's original and present community. Thus where heavy drinking is part of the 'way of life', as in France, the heavy drinker is likely to be the conformist, and "many French alcoholics are . . . initially . . . unlikely to be strikingly abnormal". On the other hand, in countries or in groups where heavy drinking and drunkenness are less widely accepted "it is, perhaps, only the deviant, the disturbed or abnormal personality, whose needs are strong enough to drive him on nevertheless". In spite of similar factors in France and Italy—which, like France, is a strong wine-drinking country—Italy has a low alcoholism rate, probably because of different popular sentiment and different dietary habits. In general, this exposition rings true, but it is only fair to add here the very insistent attempts made nowadays in France in spite of all the difficulties to fight alcoholism; to mention that according to several Italian psychiatrists alcoholism, at least in northern Italy, is by no means as uncommon as generally accepted and, finally, that in Britain a considerable proportion of alcoholics seen in out-patient clinics and hospitals seem to be basically relatively 'normal' personalities and not 'deviants', although drunkenness and heavy drinking are not generally accepted.

While an "ambivalent attitude (of society) towards alcohol is . . . relevant to the problem of Anglo-Saxon alcoholism", one has to look at personal problems to understand how particular individuals within this culture become alcoholics. Is there a specific 'alcoholic personality'? The author found even in his small sample of 72 alcoholics quite a number of different personality types, and, as he himself rightly stresses, his list is by no means exhaustive. Most common among his cases was the dependent type of alcoholic, the person who in his childhood was dependent on his mother, later on often married a woman older than himself (mother substitute) and then became dependent on her. Frequently in such cases acceptance by the alcoholic's wife of his dependence on her helped to maintain the marriage, but also his drinking "at a level consistent with the maintenance of the marriage itself". Slightly less common than 'maternally dependent' were 'socially insecure' alcoholics who, lacking the close relationship with their mother or mother-substitute, were concerned with their wider social relationships. Dr. Jones divides this group into those suffering from a general feeling of personal inferiority or inadequacy ('ego-need'), those feeling badly about themselves when participating in social situations ('socially inadequate'), and finally those who, driven by a strong need for acceptance, become extreme conformists ('socially dependent'). Common to the whole 'social insecurity' group of alcoholics is their own feeling of emotional deprivation in childhood.

The 'escapists' among the author's alcoholics—the 'narcosis' drinkers—came from varied backgrounds, but their drinking arose from an inability to tolerate difficulties, from an "unbearable stress caused to certain personality types by certain kinds of environmental experience". In a different environment such people might not have become alcoholics at all or different types of alcoholics. Finally, Dr. Jones found some alcoholics in whom sexual factors seemed to have been responsible for causing alcoholism, such as unresolved Oedipal situations or unconscious homosexuality.

Thus many different kinds of personality can become alcoholics, and, moreover, there is some overlap in background, etc., between them. Not only personality factors but also environmental conditions must be considered and studied in a 'socio-personal' approach. Alcohol, for the alcoholic, is a means of adjustment. "Alcoholism is not the invariable result of particular kinds of personality constellation, but the solution found when problems of adjustment arise because certain types of personality are confronted by certain types of environmental stress".

Early environmental factors were also found to be of great importance in the differences found between clinic alcoholics and prison alcoholics. In general, the prisoners lacked even the limited success enjoyed by the clinic patients, which the author ascribes mainly to the prisoners' lack of social assets such as education, vocational training and marriage.

The author draws certain conclusions from his investigation of prevention and treatment. Prophylaxis requires better education in the handling of family relationships. in upbringing of children, in changing of parents' emotional attitudes, as excessive drinking arises on the basis of problems dating from experience in early life. In regard to therapy, Dr. Jones favours an integration of social and personal therapy in a background of a 'therapeutic community', with group therapy, and social workers helping the alcoholic in relation to his outside environment.

The author himself stresses the limitations set by the relatively small size of his sample and its lack of being 'representative'; however, the great majority of alcoholics also in Britain do not enter prison and do not come for treatment until they are in fairly advanced stage. Many data given by the author closely resemble those found from investigations in Britain. Thus the average age of alcoholics (44), the ages at which they reached the prodromal stage (30), the 'incubation period' between first drink and start of the prodromal phase (15 years), all closely resemble the average ages found in English alcoholics. Many of the differences between clinic and prison samples described by Dr. Jones correspond to those found in Britain between alcoholics admitted to an alcoholic hospital unit on one hand, and excessive drinkers and alcoholics found in a reception centre for the homeless on the other (Glatt and Whiteley, 1958). Personality types, as described by Dr. Jones, commonly occurred among much greater numbers of alcoholics closely observed during the past ten years in Britain. The type of treatment he suggests—such as the 'the-

peutic community' approach, group therapy, the use of social workers as group therapists, etc.—has been practised in alcoholic units in Britain with success for the same period, and is the basis of the management of regional alcoholic units now recommended by the Ministry of Health. It is therefore clear that the author's findings, discussions and conclusions also are of great relevance and interest to Britain. He has certainly succeeded in his aim of studying closely the part which addiction plays in the lives of a limited number of alcoholics; and, by the presentation of data in what he calls a qualitative rather than a quantitative form, and the adoption and description of the life-history approach, he gives the reader many fascinating glimpses into the lives, individual problems and worries of alcoholics. At the same time, he is careful not to draw too far-reaching conclusions and to point out the limitations which are inevitable when studying samples of such a diversified population as formed by alcoholics. Alcoholism is a very complex subject requiring a multi-dimensional interdisciplinary approach. Anyone whose work brings him in contact with alcoholics or who is concerned with alcohol problems in general will find close study of Dr. Jones's *Alcoholic Addiction: A Psycho-social Approach to Abnormal Drinking* extremely interesting and highly rewarding.

M. M. GLATT

TWENTY YEARS OF VITAMINS AND HORMONES

Vitamins and Hormones

Advances in Research and Application. Vol. 20. Edited by Robert S. Harris and Ira G. Wool: Consulting Editors: G. F. Marrian and Kenneth V. Thimann. Pp. xvii + 707. (New York and London: Academic Press Inc., 1962.) 114*s*. 6*d*.

WITH this, the twentieth volume, *Vitamins and Hormones* celebrates twenty years of continuous publication, and the editors have appropriately invited P. Karrer and G. Pincus to mark the occasion by writing guest prefaces in which they express their appreciation of the service this publication has given to all of us working in the field. The past twenty years cover a period of extraordinary growth and development both in vitamin research and in endocrinology, and there can be little doubt that the many authoritative reviews published in *Vitamins and Hormones* have made a valuable contribution to progress, both through their critical assessment and clarification of the available information on a topic, and in providing the stimulus for further investigation.

The present volume fully maintains the standards of its predecessors, and it follows the example set two years ago and is enlarged to contain the papers contributed to the symposium on "Vitamin E and Metabolism" held in honour of H. M. Evans at Zurich in June 1962. This collection of some twenty papers and discussion by many of the leading workers on vitamin E gives a comprehensive picture of present-day knowledge of this vitamin. A felicitous account of its early history by H. M. Evans is followed by descriptions by members of the research staff of Hoffmann-La Roche of the chemistry, physico-chemical properties and assay of the tocopherols, and of the absorption and distribution in tissues of the vitamin. Probable steps in the metabolic degradation of α-tocopherol are described by C. Martins. R. S. Harris has prepared a valuable summary of the influences of storage and processing on the content of vitamin E in foods. He emphasizes that much of the published data must be considered to be qualitative, or at best semi-quantitative, for it is only recently that precise methods of analysis have become available.

The metabolic function of vitamin E is considered in detail. K. Schwarz discusses the interrelationships between vitamin E, trace elements and sulphydryl groups in the respiratory decline characteristic of liver tissue from vitamin E-deficient animals during the early stages of diet-induced liver necrosis; J. Green considers the mutual interactions of vitamin E and other vitamins and the ubiquinones; A. L. Tappel reviews some of the more recent work on the biological function of vitamin E and of selenium compounds as lipid antioxidants; J. S. Dinning summarizes the findings from his own laboratory on the influence of vitamin E deficiency on nucleic acid metabolism; H. Dam considers the relationships between vitamin E and poly-unsaturated fatty acids in experimental animals; M. K. Horwitt describes the long-term experiments he is carrying out with his colleagues on the tocopherol requirements of men and animals; H. M. Nitowsky, K. S. Hsu and H. H. Gordon discuss the vitamin E requirements of human infants; and J. Marks presents a critical evaluation of the therapeutic value of α-tocopherol in various disorders. The three remaining articles deal authoritatively with the probable metabolic functions of vitamin E in farm animals: poultry by M. L. Scott, cattle and sheep by K. L. Blaxter, and pigs by O. Swahn and B. Thafvelin. Nevertheless, neither E. C. Slater and P. György, who contribute their comments on the other papers, nor any of the authors of these papers, claim yet to see the solution of the problem of the mechanism of action of vitamin E, and the complexities of its interrelationships with selenium and unsaturated fats.

Six chapters are devoted to hormonal problems: A. I. Winegrad considers the effects of hormones on the metabolism of adipose tissue, with particular reference to the use of *in vitro* techniques for the investigation of the effects of hormones on glucose utilization, on the synthesis of fatty acids and triglycerides and on the release of free fatty acids by adipose tissue; P. J. Randle and H. E. Morgan contribute a comprehensive review of studies of hormonal and other factors which regulate the uptake of glucose by muscle; D. E. Tapley and W. B. Hatfield discuss present views of the mode of action of thyroxine; H. Breuer considers the biosynthesis, intermediary metabolism, conjugation and degradation of natural œstrogens of animal origin; A. D. Lerner and T. H. Lee contribute a short account of the studies leading to the isolation and determination of the structure of the peptides that function as melanocyte-stimulating hormones, and J. P. Mascaren and L. Machlis discuss the probability that hormonal control contributes to the directional growth of pollen tubes.

Two chapters deal with vitamins other than tocopherol: L. J. Reed gives a comprehensive account of lipoic acid and of its biological function as a prosthetic group in α-keto-acid dehydrogenase systems in animal and bacterial cells, and discusses possible other roles for this growth factor; T. B. Morgan and J. Yudkin contribute an excellent discussion of the intriguing phenomenon of the vitamin-sparing action of dietary carbohydrates. Their own studies with sorbitol have done much to clarify the situation, and it is now evident that coprophagy supplies the vitamins spared not only with sorbitol and ascorbic acid-containing diets, but also with starch-containing diets. Thus coprophagy provides the explanation of the condition of refection in rats fed on diets containing high levels of potato or rice starch.

In the remaining chapter, J. E. Kirk spans the fields of both vitamins and hormones in making a useful compilation of the available information on the content of these substances in the tissues of man and animals of various ages.

It is thus abundantly clear that this volume of *Vitamins and Hormones* worthily upholds its own high standards. May succeeding volumes continue to do so.

J. W. G. PORTER

INDUSTRIAL CANCER OF THE BLADDER

Carcinogenic and Chronic Toxic Hazards of Aromatic Amines

By T. S. Scott. (Elsevier Monographs on Toxic Agents.) Pp. xi+208. (Amsterdam and New York: Elsevier Publishing Company, Inc., 1962.) 30*s*.

THE development of the synthetic dye industry is a fascinating story full of romantic and also tragic events. As in many other passages of history, the full implications are not yet clear. As all the dyes are aromatic compounds, and so benzene derivatives, the story really began with the discovery of benzene by Faraday in 1825. Twenty years later, Hofmann isolated benzene from coal-tar. The young W. H. Perkin, working in Hofmann's laboratory in London, obtained a mauve dye by oxidizing aniline in an attempt to synthesize quinine. Perkin sent a sample of this dye, which he called mauveine, to the dyer Sir Robert Pullar of Perth. As a result of this the manufacture of the dye on a commercial scale started, and Perkin took out a patent in 1856. The red dye, magenta or fuchsin, was discovered in France in 1859. During this period Griess developed the diazo reaction while working in a Burton brewery, and the Russian chemist Zinin discovered benzidine and 1-naphthylamine. Lieberman and Schneiding prepared 2-naphthylamine in 1879.

During the past hundred years the synthetic dyestuffs industry, which is largely dependent on aromatic amines, has expanded enormously. At first the expansion was mainly in Germany and Switzerland, in spite of the fact that the first synthetic dye was discovered, manufactured and used in Britain. During the First World War, however, Britain, the United States and other countries started their own dyestuffs industry because the German products were not available. The manufacture of synthetic dyestuffs is now carried on in many countries throughout the world. Many of the intermediates are also used in the manufacture of rubber products, paper, textiles, cables, pigments and plastics.

The first fifty years of the development of this side of the organic chemical industry were full of hope and success. Occasional toxic effects in workmen were seen, due to aniline and other amines causing methæmoglobinæmia and cyanosis. Sometimes the compounds caused irritation of the bladder, but provided that the working conditions were not exceptionally bad the effects were not considered serious.

In 1895, however, Rehn, a surgeon from Frankfurt-am-Main, which was a centre of the dyestuffs industry, pointed out the incidence of bladder cancer in men employed in the industry. Rehn discussed the frequency of hæmaturia and cyanosis among the workers and considered that the bladder cancers seen in three men who had worked on the manufacture of magenta for periods varying from 15 to 29 years were due to exposure to aniline. He called the disease aniline cancer. It is now considered that aniline itself does not cause cancer, but the aniline used in the past century contained many other amines as impurities or contaminants. Magenta could not have been formed if the aniline used had been pure. As other countries took up the manufacture of synthetic dyes the industrial bladder cancer appeared some decades after the commencement of manufacture.

As the result of much long and careful investigation it was established that although aniline did not cause cancer, exposure to any of three aniline derivatives—1-naphthylamine, 2-naphthylamine and benzidine—was associated with cancer of the bladder. Later it was shown that men exposed to xenylamine (4-aminobiphenyl) or the dyestuff 'Auramine' also developed the disease. The risk from 2-naphthylamine appeared to be greatest. The manufacture of 2-naphthylamine has ceased in most countries; this is due in part to the fact that many dyes can be obtained without using the base itself. The other amines are now manufactured under improved conditions where the exposure to workers is minimal. There was, however, a delay of about half a century between the first suggestion that aromatic amines could cause cancer in man and action to prevent the hazard.

The delay was in part due to the difficulty in inducing cancer of the bladder in animals. The first species in which the carcinogenic aromatic amines induced bladder cancer was the dog. Hueper, working in the United States, produced bladder cancer by dosing dogs with 2-naphthylamine for two years. The evidence for the induction of experimental bladder cancer with benzidine is less certain; but all the amines known to cause bladder cancer in man induce cancer at other sites in rodents.

As a result of the knowledge of the hazard from these compounds the exposure has been reduced. The Association of British Chemical Manufacturers invited a committee to draw up a "code of industrial practice to cover the manufacture and use of known or suspected bladder carcinogens". The code which was drawn up, mainly by Dr. T. S. Scott and the late Dr. Michael Williams, has been approved and widely adopted. Dr. Scott, who has himself played a major part in the development of the control of these dangerous compounds, has produced an interesting and authoritative account of the chemical, technical and medical aspects of the subject.

E. Boyland

NUCLEAR ENERGY ON THE DESK

Newnes Concise Encyclopaedia of Nuclear Energy

Advisory Editors: D. E. Barnes, R. Batchelor, Dr. A. G. Maddock, J. A. Smedley and Dr. Denis Taylor. Pp. x+886+8 plates. (London: George Newnes, Ltd., 1962.) 160*s*. net.

THIS *Encyclopaedia of Nuclear Energy* has been produced "under the leadership and guidance of five Advisory Editors" all of whom are well known in their own fields. There is a foreword by Dr. H. Kronberger, but no editorial introduction nor any indication of who bears the overall editorial responsibility—a pity, since the job seems to have been well done. It is necessary, therefore, to turn to the dust cover to learn that the book provides information on "theory, techniques and applications of nuclear science", is intended for "scientists, research workers, laboratory assistants and sixth form science students for A level", and that "over seventy scientists have contributed".

Nuclear energy is a wide topic; its applications involve some nuclear physics, engineering, biophysics, solid-state physics, metallurgy, and so on. Indeed its coverage might be expected to include something from most branches of science. This expectation is well realized and the topics treated do indeed give a fair picture of the scope of nuclear energy. It is no serious criticism to say that, occasionally, as in some of the biological articles, the bounds of nuclear energy appear to be exceeded but, even so, there are one or two gaps that merit filling in a second edition. For example, I could find no article on radiation damage, although there is one on the annealing of radiation damage. Nor is there anything about neutron radiography or non-destructive testing.

There are many competent articles and some very good ones, for example, on atomic structure, atomic weapons and their effects, biological effects of radiation reactors, nuclear fission, controlled thermonuclear research, to name a few. Some of the shorter definitions (for example, those of atomic interaction and neutron diffraction) are rather trivial, and one at least, that of cold neutrons, is incorrect. The coverage of the field of

diffraction analysis, whether by X-rays, neutrons or electrons, is inadequate; but with few exceptions the quality of the articles and definitions is good at an intermediate level of knowledge. Most of the articles are less than 1,000 words in length although a few are much longer and some consist of brief definitions; but 89 pages out of a total of 886 (that is, 10 per cent of the volume) are devoted to a list of isotopes and their properties. This list is presented on successive pages and gives somewhat more information than the usual tabular form permits. I am not sure, however, that the middle of an encyclopædia is the right place for it: there might be quite a demand for a separate booklet containing the information presented.

The *Encyclopaedia* has no index, and this at once raises the problem of how easily information is to be found. This has been tackled by entering terms in more than one word order with appropriate references, and by cross-references to related articles; but only partial success has been achieved, and I think that an orthodox index might well be included in any further edition.

I did not notice many misprints—"Van der Waal's" for "Van der Waals" on p. 82, and "Zircalloy" for "Zircaloy" on p. 108 are all I spotted—but I did notice in the symbolism a lack of conformity with the usually accepted conventions. Thus we find such symbols as $_{34}Se^{70}$ instead of $^{70}_{34}Se$ throughout, and n/cm²/sec instead of n/cm² sec.

The volume is well produced, easy to read and easy to handle. It should prove to be extremely useful to those who wish to look up a point of interest without having to consult more weighty books of reference, and would seem to justify Dr. Kronberger's remark in his foreword that "its place is on the desk not on the shelf".

J. Thewlis

ASPECTS OF CHILD PSYCHOLOGY

Readings on the Exceptional Child

Research and Theory. Edited by E. P. Trapp and P. Himelstein. Pp. xii + 674. (The Century Psychology Series). (London: Published by Methuen and Co., Ltd., 1962.) 55*s*.

THIS is an excellent hand-book edited by Trapp and Himelstein, both of Arkansas University. It contains forty-eight chapters divided into sections, and covers a wider field than the title leads one to expect.

The first section is concerned with studies of children of exceptional intellectual processes and discusses not only the mentally deficient but also the intellectually gifted. This is followed by a section on exceptional sensory and motor processes, which includes the aurally and visually handicapped, the speech handicapped, the brain damaged, and the physically handicapped. A final section is devoted to emotionally disturbed children. These sections are preceded by three introductory chapters which discuss, in turn, the incidence of exceptional children (in the United States), the functional classification of exceptional children, and the meaning of research. There are also two excellent indexes, one of names and one of subjects. In addition, each chapter has its own list of references, and although each is written by a different author, the book is well compiled with a sense of continuity throughout, and reveals careful editing.

The book's sub-title *Research and Theory* probably gives a fair picture of its contents. Most of the chapters are written by well-established authorities, but there are also accounts of original research not previously published. The editors state in the preface that this is a novel feature of the book, and that their aim throughout has been to include studies which will stimulate research. The main emphasis, in consequence, is on the contemporary scene, although occasionally a subject may be treated historically because from this angle have branched many fruitful lines of investigation.

The mentally deficient child has received most attention, and seventeen chapters in all appear in this part of the book. One chapter of interest is that devoted to the concept of pseudo-feeblemindedness in which the work of the Clarkes is mentioned, one of the few references to British psychologists. The author of this chapter distinguishes two meanings of pseudo-feeblemindedness which are mutually exclusive. One occurs when a mistaken diagnosis has been made, the other is described as a condition of mental deficiency which can be ascribed to factors other than those customarily held to be the conditions of mental deficiency. The writer complains of the indiscriminate usage of this term, and the failure to separate these two meanings. Even in the same article or report they may be confused.

Other chapters in this section include a historical survey, the concept and classification of mental deficiency, and the measurement of rigidity. The latter by Zigler is a well-written and valuable study with a critical survey of the work of Lewin, Kounin and Goldstein. There are also chapters on different aspects of learning and of reasoning in the mentally deficient. The final chapter in this section considers the effects of a severely mentally retarded child on the family, an important consideration. These titles may serve to indicate the scope of this portion of the book.

Terman's longitudinal studies of the gifted child form the focal point of the next section, and a useful summary is given of this research. It contains an account of the data obtained at school age, and traces the careers of the children from school to their subsequent life-work and status at middle-age. The contributions provide supplementary interesting material on the educational and personal problems centring round the highly intelligent child. The attitude of teachers of gifted children is described as negative in some instances.

The deaf and the blind are adequately presented and point the way to further research. Writings on the brain damaged and on the physically handicapped occupy eleven chapters, all of them are absorbingly interesting and yield valuable information of recent studies. These include studies of disorders of conceptual thinking in the brain-injured child, and the use of certain perceptual measures of brain injury with mentally retarded children. Other relevant discussions, to mention a few of them, are concerned with the effect of distraction on the performance of brain-injured; concrete and abstract thinking in organic and non-organic mentally retarded children; motivation, adjustment and anxiety of cerebral-palsied children.

The final section (Part 4) of the hand-book gives some indication of the problems of emotional difficulties, and although there are only six chapters in this section, they provide interesting reading. School phobia is discussed as is also the use of tranquilizers. The present trends in schizophrenic research and its implications for childhood schizophrenia form the material of one contributor, followed by a separate discussion by a different author on the parental attitudes of mothers of schizophrenic, brain-injured, retarded and normal children. Other chapters in this section are equally important.

Considered as an entirety, this is a valuable book. The title is misleading because it is delimiting. The contents are more than readings; they are sources of information and incentives for research. The term 'exceptional children' has a wider connotation in the text than the generally accepted definition. This book can be recommended to all interested in children, and to professional workers of different disciplines. It will also serve as a guide to students in the fields covered in the text, and certainly will be a valuable addition to many libraries. It is also an excellent supplementary book to students of child psychology.

Mary Collins

RUTHERFORD AND THE ATOM

POETIC PORTRAYAL OF A SCIENTIFIC DISCOVERY

By Prof. JOHN FRANCIS

Department of Veterinary Preventive Medicine,
University of Queensland, Brisbane

THE whole structure of our everyday world is dependent on scientific knowledge, and this knowledge has profoundly influenced philosophy. It is therefore surprising that the romance of scientific discovery has received such slight attention from the poets[1].

A notable exception is the poem on Rutherford by Douglas Stewart[2] of some thirty-six verses. One of these tells of the young New Zealander's reaction when he learned of his appointment to Cambridge:

"I'll dig no more potatoes!" so he had vowed
That day the telegram from Cambridge came,
And dug no more indeed, nor milked nor ploughed
Except in the great seas of thought and fame;
So he stood now, Lord Rutherford of Nelson.

Another verse describes him engaged in his research:

Mostly too busy to think—too busy thinking.
But thinking was doing; there was such satisfaction
Watching those tiny comets darting and winking
It really left no time for speculation.
Thought would go outwards, expansion; his was a shrinking,
How to get mind and hand so small, that was the problem,
That in one final thrust of concentration
They would be able to move inside an atom.

Other verses link his scientific work with his father's craftsmanship and the New Zealand countryside:

That craftsman's hands still moving inside his own.
It was a haunted place, this tower of knowledge,
Calm with old books but wild with thoughts unknown,
All dark except for lamps like lights of courage
Where lonely scholars sought for truth in stone.
It shut the whole world out from a man and his work;
But while the white stars glittered above the college
A wheel moved somewhere far away in the dark—

That waterwheel of his father's lifted up
Water and sunlight in its wooden hands . . .
In long-lost Nelson wheels that his father had made,
And good wheels too, were serving the people still . . .

The universe turned and moved above him so vast,
Full of black space, the huge wheel slowly spinning,
He knew he stood with his specks of radiant dust
Not at the end of things but at the beginning.
What was he now but that small lump of a boy
Who made his own miniature wheel to splash in the water
Such ages ago; working all day in the joy
Of pure and bubbling creation, copying his father:

The social implications of atomic energy are described, together with the great fascination of the quest for discovery and achievement:

Take off his trappings and, naked, hungry and fierce,
All over the earth, in jungle or civilized city,
Men were but savages yet; God help the poor brutes,
For this new power, appalling to love and pity,
Was force that no savage yet had dreamed of wielding.
Then you could turn away, pack up and go home,
Dismantling the apparatus. He'd have his herd of Jerseys,
And up in the dawn to milk then, hitch up the cart,
Off to the factory to yarn with others of his type
(Looked like a farmer, always a farmer at heart,
Corpulent, bushy-moustached, smoking his pipe) . . .

But he had grown to like
This life of power where scientists met together
And felt they were priests and rulers. He liked to talk
With his great peers that language wrapped in mystery—
But he'd be plain if he could. No, it was rather
He liked the thought that what he touched was history.

Then the triumph of discovery and Rutherford's final belief that the essential goodness of the world would prevail:

He was so clumsy and blind, beyond all patience:
But out of the dark, from nowhere, flashed the conception
Like force in the atom and filled him with its radiance;
And steadily, patiently, always in the right direction
Despite his stumblings it moved in him in silence
Until at last what it wanted to do was done.
All things, it seemed, moved through time to perfection,
Through earth and wood and flesh, through the mind of man . . .

And when the old passions were roused and blood was spilt
What else could man do but stand against the marauder?
That was the thing that must change, this pattern of savaging.
For never had there been such a weapon since time began
And men who would stop at nothing might stop at fear . . .

And yet as he looked at the sky so dark with warning
Vast over earth and its towers, the night heaved over
Close and familiar as a waterwheel turning
And shed its stars like drops of crystal water
And radiant over the world lay the clear morning.
Men moved in darkness truly, but also in the sun
And on that huge bright wheel that turned for ever
He left his thought, for there was work to be done.

These extracts may give some idea of the poem, which provides a unique impression both of Rutherford and of scientific discovery.

Fitzgerald[3] has appraised the diverse literary work of Douglas Stewart, and his radio play, *Fire on the Snow*, which describes Scott's epic journey to the South Pole, is well known. Many of Stewart's poems do not have the same quality as *Rutherford*, but *Elegy for an Airman* (1940) shows the same feeling for the New Zealand countryside. Then, after arriving in Australia, Stewart achieved the feat of displaying the same powers of observation and visualization to capture the spirit of a harsh, dry landscape in his *Birdsville Track*[4].

Obviously, however, *Rutherford* goes far beyond these poems, as it combines Stewart's feeling for the countryside, his father's craftsmanship and the life of a peaceful agricultural community, with a dramatic portrayal of the greatest scientific discovery of the age. He also shows a fine appreciation of the social implications and finally expresses his faith in human survival.

Fitzgerald describes the poem as "a towering concept . . . as a work of art it is a masterly piece of design and integration".

Rutherford obviously has a special appeal to scientists, and I feel sure that it will remain memorable as a major attempt at the poetic portrayal of a scientific discovery.

[1] *Times Literary Supplement*, 153 (March 1, 1963).
[2] *Rutherford and Other Poems* (Angus and Robertson, Sydney, 1962). *Rutherford* was first published in *Quadrant*, **14**, 30 (Sydney, 1960).
[3] Fitzgerald, R. D., *The Elements of Poetry; Motif in the Work of Douglas Stewart* (Univ. Queensland Press, 1963).
[4] *The Birdsville Track, and other Poems*, 29 (Angus and Robertson, Sydney, 1955). *The Birdsville Track* was first published in *The Bulletin*, 18 (October 22, 1952).

Although many will agree with Prof. Francis that scientific discovery has received but slight attention from the poets, on the other hand there have been, and still are, men of science who were or are also good poets. One need only mention the late Sir Ronald Ross and the late Sir Charles Sherrington and Prof. E. N. da C. Andrade

and also refer to the poem "Death of a Laboratory" recently published in *Nature* (194, 711; 1962), which was acclaimed by many readers. This poem was written by D. Bolton, who is a chemist.

Attention should also be directed to the book on the poetic relations of science and technology by W. Eastwood, reviewed in *Nature* (192, 98; 1961) by T. R. Henn, lecturer in poetry and drama in the University of Cambridge, whose own Hatfield Technical College lecture on "Science and Poetry" was published in *Nature* (191, 534; 1961).

Here are the 'two cultures' meeting on a common ground—that of poetry; but so far it would seem that the scientists have moved more than half-way. Poets such as Douglas Stewart are helping the other side to gather momentum. To-day science is presenting a great canvas to the world; perhaps there would be fewer disparaging remarks among non-scientists concerning science and scientists if artists of all types, especially painters, poets and novelists, began to cover that canvas with material which might capture the imagination and perhaps even the admiration of the scientific and non-scientific world.

Even in technology there is beauty; but it needs the right man to reveal it. The day must come when science is accepted for what it is—the revelation of the truth. Then there will be no need to argue about 'two cultures' (or indeed any number of cultures); for, with the help of the arts, literature, music and science the entire world will become civilized and cultured. Sir Thomas More's perfect social and political system will no longer be imaginary or unpractical, it will be real. [EDITOR.]

THE INTERPLANETARY MAGNETIC FIELD

By PROF. V. A. BAILEY
Emeritus Professor of Physics, University of Sydney

(1)

ALTHOUGH the magnetometers of the space probes *Pioneer* 5, *Explorer* 10 and *Mariner* 2 have now provided much information on the interplanetary field $\boldsymbol{F}_i$, the published discussions of this information have left many serious obscurities in our conception of this field and no reliable idea of its origins. (This opinion is expressed clearly in the comment (*a*) of Dr. E. J. Smith (Jet Propulsion Laboratory, Pasadena) quoted in Section 4 of this article.) For this reason it is here proposed to subject the magnetic data and the concurrent plasma data to a new fundamental analysis.

It will then be seen that this new analysis has justified itself by revealing a new and important aspect of the data which seems to have been completely overlooked in the publications on the three space probes.

(2) Data from *Pioneer* 5 during March 11–April 30, 1960

Magnetic data obtained from *Pioneer* 5 are given in publications by P. J. Coleman, C. P. Sonett, D. L. Judge and E. J. Smith[1] and by P. J. Coleman, Leverett Davis and C. P. Sonett[2]. These authors reported "the apparent existence of a quiet-time field perpendicular to the ecliptic"[1].

The magnetometer on *Pioneer* 5 measured only the component $B_\perp$ which was transverse to the spin axis of the vehicle. But since there was no obvious change of quiet-time $B_\perp$ as this spin axis changed its inclination to the Earth–Sun line from 27° (on March 11) to 2° (on April 8) and then back to 22° (on April 30) it was concluded that $B_\perp$ was approximately perpendicular to the plane of the orbit and therefore also to the ecliptic.

During the period March 31–April 3 the magnetometer also recorded the occurrence of a magnetic storm field $\boldsymbol{B}_s$ at the same time as a similarly varying storm field $\boldsymbol{F}_s$ was observed at the Earth.

All these data were used later by me[3] to infer the sense of the perpendicular quiet-time magnetic vector $\boldsymbol{B}_q$, and it was found that very probably:

$\boldsymbol{B}_q$ was directed from north to south of the ecliptic plane (1)

(3) Data from *Explorer* 10 during March 25–27, 1961

Explorer 10 was launched for the purpose of obtaining vector magnetic field and plasma flux measurements along a trajectory which extended into the interplanetary medium up to a distance of 42·6 Earth radii from the Earth.

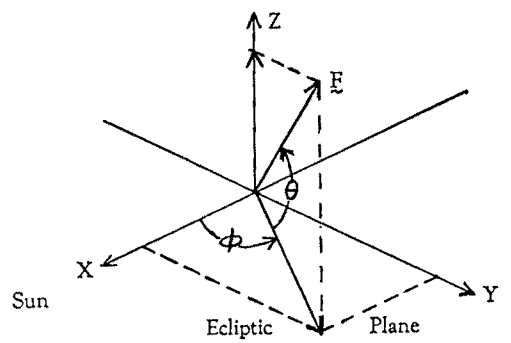

Fig. 1

Magnetic data from this probe are given in a publication by J. P. Heppner, N. F. Ness, C. S. Scearce and T. L. Skillman[4], and are there discussed and interpreted with the help of the corresponding plasma data published by the "MIT group". The magnitude and direction of the field vector $\boldsymbol{F}$ are there expressed mainly by means of the ecliptic co-ordinates F, θ, φ shown in Fig. 1.

The summary of this publication is set out in eight paragraphs in their Section 17.

Various conclusions are to be found in this summary, the most interesting of which relate to a hypothetical "large-scale cavity".

For example, paragraph 3 states that at distances > 22 Earth radii and before a particular sudden commencement, the field is typically oriented in one of three directions, designated regions A, B and C, which correspond to three distinctly different levels of average field intensity. Region A alone correlates with the absence of plasma and is interpreted as lying within the cavity. Regions B and C are observed only at the same time as plasma and lie more than 30 and 23 Earth radii respectively from the Earth.

Paragraph 6 states, "The cavity characteristics indicated by the measurements do not agree in detail with the theoretical cavity models".

Paragraph 7 states "the fields measured external to the geomagnetic cavity are interpreted as fields of solar-interplanetary origin".

Lastly, paragraph 8 states that the tendency of given field conditions to persist indicates that the solar wind possesses structure with dimensions of the order of 0·01 A.U.

Nowhere in this summary or in the rest of the paper is there any reference to the fact, shown by Figs. 25–27,

that in all the regions, A, B and C, the average magnetic field vectors slope downwards, that is:

they have components which are perpendicular to the ecliptic plane and are directed from north to south (2)

This fact is confirmed by the curves in Figs. 12–17, which represent the values of the inclination θ of the total field vector ($\boldsymbol{F}_t$) to the ecliptic plane, before the sudden commencement (*SC*) indicated in Fig. 17; for the values of θ are there negative during 98 per cent of the journey between the distances 12 and 41 Earth radii from the Earth. It is also confirmed by the statistical distribution of values of θ shown in Figs. 23*a* and *b*.

The absence of mention of this fact by the authors suggests that they were concentrating on behaviour of the magnetic field in accordance with certain orthodox ideas and principles in physics and astronomy.

The vectors in Figs. 25–27 and the curves in Figs. 12–17, which represent the azimuthal angle φ (defined in Fig. 1), show that the components F_x, F_y of $\boldsymbol{F}_t$, which lie in the ecliptic plane, frequently change their directions.

In this regard they differ profoundly from F_z, the component perpendicular to the ecliptic, which, about 98 per cent of the time, has only one direction, namely, from north to south. These facts are also illustrated by the vectors shown in Fig. 31.

These facts seem to point to the conclusion that the observed interplanetary field vector $\boldsymbol{F}_t$ is the resultant of at least the following two kinds of magnetic vectors $\boldsymbol{A}$ and $\boldsymbol{B}$:

$\boldsymbol{A}$ has all its three components A_x, A_y, A_z variable in direction;
$\boldsymbol{B}$ is perpendicular to the ecliptic and always directed from north to south (3)

Thus:

$$\boldsymbol{F}_t = \boldsymbol{A} + \boldsymbol{B} \qquad (4)$$

(4) Data from *Mariner* 2 during late August and early September, 1962

The most recent available scientific report on the magnetic data from *Mariner* 2 in interplanetary space is that published on December 7, 1962, by P. J. Coleman, jun., Leverett Davis, E. J. Smith and C. P. Sonett[5]. For convenience their abstract may be quoted here in full:

"Preliminary analysis of *Mariner II* magnetometer data indicates a persistent interplanetary field varying between at least 2 and 10 gamma. The interplanetary field appears to lie mainly in the ecliptic plane, although there is a substantial, fluctuating, transverse component. The *Mariner II* data agree reasonably well with the prior *Pioneer V* observations. Typically, variations as large as 5 to 10 gamma in the field component radial from the sun are measured. Correlations with the *Mariner II* plasma measurements have been observed".

Some care is needed here in comparing their data with those of *Explorer* 10 because their report used a notation for the co-ordinate axes which differs from that used in my Fig. 1. It appears that after *Mariner* 2 was stabilized (on September 3) their co-ordinates X, Y, Z were related to the co-ordinates X, Y, Z in Fig. 1 as thus shown:

	Perpendicular to—	In—	the ecliptic plane
Mariner 2	X	Y	Z
Fig. 1	Z	Y	$-X$ (X is sunwards)

Thus their symbols B_x, B_y, B_z represent respectively the components along the Z and Y axes in Fig. 1 and the component against the X axis in Fig. 1, and so positive B_x is directed northwards perpendicularly to the ecliptic plane and positive B_z is directed radially away from the Sun.

Since only the variations ΔB_z of the radial component were then known we shall here consider the components B_x and B_y alone. The values of B_x and B_y during the period 06·00–06·50 G.M.T. on September 3 are alone given in this report, namely, by means of the top right-hand curves in its Fig. 2 (p. 1100).

The curve for B_x shows that in that period B_x was always negative and so we conclude that then:

there was always a component of the field perpendicular to the ecliptic and directed from north to south (5)

This is in exact agreement with the conclusions (1) and (3) derived from the data of the other two space probes.

The curve for B_y shows that in this period $\boldsymbol{B}_y$ did not change its direction.

The authors also state, "Our earlier speculation [in *Phys. Rev. Letters*, 5, 43 (1960)] that in very quiet periods the transverse component might be mainly perpendicular to the ecliptic plane is inconsistent with the *Mariner II* data for this period". Reference back to their paper of 1960 shows that in fact there was no change in $B_\perp$ as the spin axis of *Pioneer* 5 changed its inclination to the Earth–Sun line by about 23°, and so their "earlier speculation" was a necessary inference and now shows that at that part of the solar cycle the two components in the ecliptic plane were relatively much smaller in value than the same components were in August–September 1962.

In the *NASA News Release* of 10.00 a.m., October 10, 1962, one of the aforementioned authors, Dr. E. J. Smith, made the following statements about the *Pioneer* 5 and *Mariner* 2 magnetic data:

"(*a*) we don't really understand where interplanetary fields come from.

"(*b*) The present theoretical concept is that these fields are drawn fron the surface of the sun and into interplanetary space.

"(*c*) But it was observed during *Pioneer V* measurement that at certain times the field obtained a very steady value. For long periods of time, the order of an hour or two, the variations were essentially negligible. This, which was a surprising result to many scientists, has been observed also on the *Mariner II* magnetometer.

"(*d*) It was anticipated, on the basis of certain theoretical models, that this transverse component would lie in the plane of the ecliptic. The *Mariner II* results, however, indicate that there is typically a substantial component which is perpendicular to the plane of the ecliptic".

To the last statement (*d*) the remark may now be added that this substantial component is most probably directed from north to south.

(5) General Discussion

The most important general conclusion which now emerges from the combined data obtained from *Pioneer* 5, *Explorer* 10 and *Mariner* 2 is that which includes the special conclusions (1), (2) and (5), namely, the statement (4) that the interplanetary field vector $\boldsymbol{F}_t$ is normally composed of two vectors $\boldsymbol{A}$ and $\boldsymbol{B}$ which are characterized under (3).

The vector $\boldsymbol{A}$ can be provisionally analysed into the radial and transverse components of E. N. Parker's well-known field drawn out of the rotating Sun by the solar wind[6] and also a component representing generalized magneto-ionic waves propagated in the magnetized plasma and originating at the Sun.

The vector $\boldsymbol{B}$ was a surprising discovery for the great majority of physicists, except possibly F. Hoyle (1958) and J. W. Dungey (1960), as may be seen from the discussion by Coleman *et al.*[2] of the quiet-time field recorded by *Pioneer* 5; for practically every known model, except one, for producing interplanetary fields was there considered and then dismissed.

The exception was first given in an article by me[7] published on May 14, 1960. This particular article did in fact predict that a negatively charged Sun could set up

in a frame of reference accompanying the Earth a magnetic field H_r which is perpendicular to the ecliptic and directed from north to south. On the last page of this article it was also pointed out that a test of this model could be made "by means of satellite-borne magnetometers", and this is what is incidentally being considered here. The same model and test were more fully discussed in three later publications[8–10].

A more recent development of this model will be published elsewhere. This, by taking account of the polarization of the plasma constituting the solar wind, can account for the observed perpendicular fields $\boldsymbol{B}$ in magnitude as well as in direction and sense, and also can account for the larger changes in $\boldsymbol{B}$ produced by solar disturbances.

As implied in Dr. E. J. Smith's statement (*a*) in Section 4, apparently no other model has been successfully proposed which accounts for a field like $\boldsymbol{B}$.

Summarizing, we may now regard the observed interplanetary field $\boldsymbol{F}_t$ as due to motion of the magnetometer relative to a negatively charged rotating Sun from which magnetic lines of force are drawn out into space by a flow of plasma clouds and from which solar disturbances are propagated as generalized magneto-ionic waves.

This hypothesis promises to cover all the facts discovered hitherto. Accordingly it may be used to make testable predictions about the magnetic data from *Mariner* 2 which have not yet been published, as well as predictions about the magnetic data from the future space-probe which it is planned to launch towards Mars.

These predictions will include a possible variation of the magnitude of $\boldsymbol{B}$ inversely as the cube of the distance of the probe from the centre of the Sun[10]. Thus, as obtained from *Mariner* 2, $\boldsymbol{B}$ will perhaps be found to have increased by the factor $(1{\cdot}5 \times 10^8/1{\cdot}1 \times 10^8)^3 = 2{\cdot}05$ when in the neighbourhood of Venus.

These predictions depend on the assumption that when the Sun is quiet the screening effects due to interplanetary polarized clouds of plasma may be nearly constant in the region between the Earth and Venus.

Many other simple and testable predictions follow from this hypothesis.

(6) Conclusion

It is important to enquire why the fact that the quiet-time field component perpendicular to the ecliptic is almost always directed from north to south has not been pointed out in the publications of the eight principal physicists concerned.

That it is a crucial fact cannot be doubted since, as we have seen, no orthodox theory exists which has explained it satisfactorily. It emerged only because I was looking for evidence bearing on the unorthodox hypothesis that the Sun carries a large negative charge. This demonstrates clearly the heuristic value of the hypothesis.

Certainly this hypothesis appears to contradict terrestrially ascertained laws of electromagnetism and electronics. But that is not necessarily fatal since we have no reliable knowledge about the magnetic fields inside a star like the Sun, which often throws up to its surface such immense and intense fields as those existing at and near sunspots, and therefore (for all we know) even more immense and intense magnetic fields in the solar interior may exist at some places and trap an excess of electrons. Alternatively the hypothesis may result from some unorthodox process in the solar interior like the apparent continual creation of electricity which has been postulated in earlier publications[7,8]. Consequently this hypothesis cannot be dismissed until it has first been thoroughly tested by means of instrumented satellites. The tests by means of *Pioneer* 5, *Explorer* 10 and *Mariner* 2 at present seem to support it.

The gap between the orthodox and unorthodox views is fortunately now being reduced by a tendency to admit the possibility that different space charges can exist in the inner and outer regions of the radiation belts[11] and that large net electric charges exist on the Moon, Venus and Mercury[12,13], which enable these bodies to influence certain terrestrial events such as the occurrence of precipitation, ice-nuclei and micrometeorites in the atmosphere and of geomagnetic storms.

We can now see that it has become essential to have some future space probes carry devices which can determine the concentration of the protons and electrons separately or else the concentration of the protons and of the excess charges per unit volume of the plasma. It would also be of great value to have them carry a device for measuring ambient electrostatic fields ranging from 10 to about 1,000 V/cm; a plate attached to an electrometer and periodically screened by 'a 'grounded' rotating sector might serve for this purpose.

Note added in proof. A report by L. J. Cahill and P. C. Amazeen (*J. Geophys. Res.*, 68, 1835; 1963), on the magnetic data from *Explorer* 12, likewise verifies the predictions from my hypothesis about the Sun.

BIOLOGICAL BASIS OF PERSONALITY*

By Prof. H. J. EYSENCK

Institute of Psychiatry (University of London), Maudsley Hospital, London, S.E.5

LIKE other sciences, psychology has the dual task of: (*a*) describing accurately, and preferably quantitatively, the material which forms its subject-matter, that is, behaviour; (*b*) of producing a causal theory which deduces the observed behaviour patterns from more fundamental causes. As human beings are biological organisms, it seems reasonable to expect that ultimately these causes should be looked for in the constitutional endowment of the person, that is, in certain physiological, neurological, biochemical and endocrinological properties of his body. Genotypic variations along these lines will, of course, interact with the environmental influences to produce the phenotypic behaviour patterns which we can observe and describe, and it is not part of our thesis to deny the importance of environmental differences. However, social psychologists, clinical psychologists and others have, in recent years, stressed environmental influences to the almost complete exclusion of biological factors, and it seemed desirable to redress the balance to some extent by stressing certain facts supporting the view that bio-

* Substance of the Thomas Young Lecture delivered at St. George's Hospital Medical School on June 17.

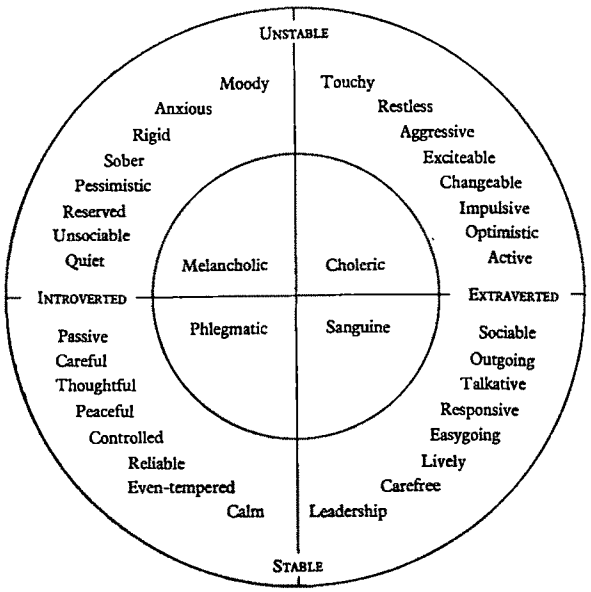

Fig. 1. Diagram showing medieval typology (inner circle) and modern personality description in terms of correlational analysis of trait measurements (outer circle) (ref. 7)

logical factors were of considerable importance in the genesis of individual differences and personality.

Descriptively, there is now considerable agreement among experts that a large part of personality can be reduced to the interplay of two dimensions, one of which is usually labelled extroversion–introversion, the other emotionality, neuroticism, or instability as opposed to stability. This theory goes back at least as far as the great medieval physician Galen, and his doctrine of the four temperaments, and the relation between these temperaments and our two dimensions is shown in Fig. 1; the outer ring of this figure shows the results of large numbers of factor analytic studies of ratings and self-ratings, carried out by such workers as Cattell, Guilford and myself. There is considerable agreement at this descriptive level between medieval theory and modern discovery[1].

My main reason for assuming that these personality dimensions do in fact have a constitutional basis lies in the results from large numbers of experimental investigations carried out on identical and fraternal twins, showing that with respect to both extroversion and neuroticism, identical twins are very much more alike than are fraternal twins. This, of course, is also true with respect to intelligence, and in line with modern genetic theories it is commonly interpreted as providing strong evidence for the hereditary nature of these traits and abilities. The criticism has sometimes been made that possibly identical twins, being so alike, are also treated more alike by parents, teachers, etc, than are fraternal twins who resemble each other less closely. If this were true then the general argument would be weakened, and one would be forced to put a great deal of weight on an interaction effect between heredity and environment. The recent work of Shields[2], however, suggests that this criticism is not, in fact, valid. In addition to fraternal twins, he examined identical twins brought up separately, as well as identical twins brought up together, and with respect to intelligence, extroversion and neuroticism, he found that identical twins brought up separately were, if anything, more alike than identical twins brought up together. The actual figures of the inter-class correlations were as follows, listing first the value for the twins brought up separately, and secondly, the value for the twins brought up together: intelligence, 0·77 and 0·76; extroversion, 0·61 and 0·42; neuroticism, 0·53 and 0·38; for fraternal twins the values were: 0·51, −0·17 and 0·11. These results leave very little doubt about the importance of the part which heredity plays in the genesis of these personality dimensions.

The genetic argument can be extended in various ways. Recent work in Germany, for example, has shown that investigations of familial similarity with respect to extroversion and neuroticism show a degree of relationship to consanguinity, which also strongly supports the hypothesis of inheritance. Another line of argument is derived from the fact that criminals, psychopaths and children suffering from behaviour disorders tend to lie in the 'choleric' quarter so far as personality is concerned; in other words, they tend to be extroverted and unstable. Following the work of Lange in Germany on "Crime as Destiny" much effort has gone into the task of locating criminals with twins and checking whether these twins were concordant or discordant with respect to criminality. So far as adults are concerned, out of 225 twin pairs 71 per cent were concordant among identical twins, but only 34 per cent among fraternal twins. So far as childhood behaviour disorders are concerned, the proportions are 87 per cent and 43 per cent, respectively. For juvenile delinquents the proportions are 85 per cent and 75 per cent. Altogether these figures again strongly support the hypothesis that genetic factors are of considerable importance in the genesis of these particular behaviour patterns.

When we come to look for a biological basis for our two dimensions of personality, we find relatively little difficulty in relation to neuroticism, emotionality or instability. Persons high on this dimension are characterized by very strong emotional reactions to all classes of stimuli, and there is a well-recognized relationship between emotional reaction and the activity of the autonomic nervous system, particularly its sympathetic branch. There is also evidence, again relating largely to twin studies, strongly reinforced by breeding experiments in animals, that the lability of the autonomic nervous system is, to a considerable extent, determined by hereditary factors. There seems little reason to doubt that the biological basis of individual differences in emotionality is closely connected with the activity of the autonomic nervous system[1].

This conclusion needs certain qualifications, particularly in view of the recent findings in the United States of considerable response specificity in the reaction of the autonomic nervous system. Thus it is found that the autonomic nervous system does not act as a whole, but that certain sub-systems may be activated much more strongly than others. It has been found that this specific innovation is characteristic of a given person even though many different types of stimuli may be utilized, and it has been found that this response specificity is preserved over periods of time extending to several years at least. It is likely that this specificity itself is inherited; it represents, as it were, specific areas of strength and weakness of the autonomic nervous system, with the latter acting as a kind of fuse which may be blown in the case of a neurotic breakdown.

When we turn to extroversion–introversion no obvious identification with any structure in the nervous system can be made, but we hope to show that even so it is not impossible to formulate certain hypotheses which have some limited support in the experimental evidence. The beginning of a theory resulting in such a link-up may be found in the postulation by modern learning theories, following Pavlov, of the importance of excitatory and inhibitory potentials in accounting for a large number of laboratory phenomena. In relation to inhibition, for example, it is postulated that massed practice on any task produces inhibitory potentials which depress the quality of the performance which is being practised, so that subjects working under conditions of spaced practice will show superior performance. It is also maintained that this inhibition, being a kind of cortical fatigue state, will

ACADEMIC PRESS London and New York

Evolutionary and Genetic Biology of Primates

In two volumes

Edited by JOHN BUETTNER-JANUSCH

Volume 1, October 1963, 327 pp., 86s.

The extensive survey of contemporary research on the Primates in these two volumes includes a review of relevant studies, much hitherto unpublished material and new work on fossils, biochemical genetics and cytogenetics, modern analyses of display and manipulative behaviour, and the histochemistry and histology of the skin as well as studies of the anatomy and physiology of the Primates.

The chapters are written by specialists in anthropology, anatomy, cytogenetics, zoology, virology, and ethology.

Volume 2—In preparation.

The Chemistry and Function of Proteins

Second Edition of **Chemistry and Biology of Proteins**

By FELIX HAUROWITZ

September 1963, 455 pp., 80s.

Reflecting the enormous advances made in the study of protein structure and function, this work is a ninety per cent revision of Professor Haurowitz's earlier work, **Chemistry and Biology of Proteins.**

Section I presents clear and concise descriptions of the isolation of proteins, their purification, methods for their partial hydrolysis and for the determination of the amino-acid sequence. Complicated mathematical treatment has been avoided, and the physico-chemical problems are treated in a manner understandable to scientists with a limited background in physical chemistry. Problems of conformation and its changes are also discussed in this section.

Section II consists of a systematic discussion of the most important classes of hormones, antigens and antibodies, and the conjugated proteins. The interaction of proteins and nucleic acids, the problems of protein biosynthesis, and the coding problem are critically discussed in the last chapter.

Germfree Life and Gnotobiology

By T. D. LUCKEY

October 1963, 510 pp., 125s.

This is the first complete work to cover this new area of biological science. From both the phylogenetic and historic viewpoints, it covers theory, problems, development, and practice.

Applications in related fields are treated briefly. Consideration of single cell isolation as the base for germfree research is followed by a review of techniques involving sterile plants and axenic invertebrates. The methods, problems, and apparatus for rearing and feeding germfree vertebrates is then detailed, and the animals are characterized morphologically, biochemically, immunologically, and physiologically. Abnormalities in form and function are examined. A particularly important point in the work is a treatment of the effect of the innoculation of specific micro-organisms into germfree animals to evaluate the role of different micro-organisms in malnutrition, shock, radiation sickness, dental caries, dysentery, and the development of different defense mechanisms.

Since germfree research is an interdisciplinary problem, the material is presented at a semi-technical level. The text is supplemented with photographs, figures, tables, and a chronology.

Fluorine Chemistry

A Multi-Volume Treatise

Edited by J. H. SIMONS

Volume 3 : [Biological Effects of Organic Fluorides

By HAROLD C. HODGE, FRANK A. SMITH *and* PHILLIP S. CHEN

November 1963, 240 pp., 80s.

Chapters on :

Fluoroacetate

Phosphofluoridates

Acute Effects of Organofluorine Compounds in Experimental Animals

Effects of Acute Doses of Fluorine-Containing Organic Compounds

Chronic Experimental Intoxication

Miscellaneous

Modern Polarographic Methods

By HELMUT SCHMIDT *and* MARK VON STACKELBERG

Translated from the German by R. E. W. MADDISON

September 1963, 99 pp., 44s.

Recent developments in polarography, a specialized branch of electro-chemistry, are summarized and reviewed in this new work. The advantages and disadvantages of new procedures, as well as their significance for chemical analysis and the resolution of scientific problems, provide a working theme. Particular attention is given to D.C. and A.C. polarography including strobe polarography, square wave polarography, pulse polarography, and radio frequency polarography.

As an advanced work, *Modern Polarographic Methods* will be of interest to industrial research workers as well as advanced university students.

Recent Progress in Hormone Research

Proceedings of the 1962 *Laurentian Hormone Conference*

Edited by GREGORY PINCUS

Volume 19, September 1963, 750 pp., 157s. 6d.

This latest volume continues the theme of this serial publication—to present the latest developments and newest challenges to the investigative mind. In dealing with subjects such as methodology, glandular normalities and abnormalities, cellular chemistry, and organismal adaptations, Volume 19 reflects the ever broadening scope of endocrinology.

Fourteen detailed papers, each followed by an extensive discussion, comprise five sections : Physical Methods in Hormone Research, Steroid Hormones, Hormones and Cellular Metabolism, Thyroid Hormone, and Comparative Endocrinology.

Pergamon Press Books

HYPOTHYROIDISM

Edited by K. R. CRISPELL, *University of Virginia*

A definitive review of hypothyroidism—the first single book to cover the entire subject. It contains contributions by leading investigators, dealing with such topics as iodine metabolism, the diagnosis and treatment of hypothyroidism both adult and juvenile, metabolic abnormalities in hypothyroidism, and the comparison between this disease and hypometabolism.

Contents include: The metabolism of thyroid hormones as related to protein binding—L. E. BRAVERMAN and S. H. INGBAR; Alterations of protein metabolism in myxedema—K. R. CRISPELL, G. WILLIAMS, G. HOLLIFIELD and W. PARSON; Thyroiditis and hypothyroidism—G. A. SMART and S. G. OWEN; Occult hypothyroidism and "Metabolic Insufficiency"—W. MCK. JEFFRIES.

174 pages Fully illustrated **55s. net ($8.50)**

AGARDograph 59, THE EFFECT OF DISTURBANCES OF SOLAR ORIGIN ON COMMUNICATIONS

Edited by G. J. GASSMANN, *Air Force Cambridge Research Laboratories, Bedford, Massachusetts*

Contains the papers presented at a Symposium of the Ionospheric Research Committee, held recently at Naples. The experimental data included make the book of great importance to those concerned with ionospheric research and practical communications.

Contents include: Comparison of solar flare effects in the D and E region of the ionosphere—K. BIBL; The problem of arctic communications following solar disturbances; Discussion—S. C. CORONTI, G. E. HILL and R. PENNDORF; On the effect of solar disturbances on the low-radio-frequency ionosphere reflection process; Discussion—J. R. JOHLER and J. D. HARPER, JR.

Published on behalf of the Advisory Group for Aeronautical Research and Development.

359 pages Numerous illustrations **£5 net ($14.00)**

VENOMOUS AND POISONOUS ANIMALS AND NOXIOUS PLANTS OF THE PACIFIC REGION

Edited by H. L. KEEGAN, *Department of Preventive Medicine, Brooke Army Medical Center, Houston, Texas* and W. V. MACFARLANE, *The John Curtin School of Medical Research, Australian National University, Canberra*

The proceedings of a symposium at the 10th Pacific Science Congress held in Honolulu. It provides a picture of the public health problem posed by venomous and poisonous animals and noxious plants in the Pacific area, and gives results of recent investigations on this subject.

Contents include: The pain-producing properties of the stinging tree, Laportea—W. V. MACFARLANE; Leeches as pests of man in the Pacific region—H. L. KEEGAN; Studies on Bombay snakes: Snake farm venom yield records and their probable significance—P. J. DEORAS.

468 pages Many illustrations **£7 net ($21.00)**

CHEMISTRY IN NUCLEAR TECHNOLOGY

S. PETERSON and R. G. WYMER, *Oak Ridge National Laboratory, Tennessee*

Provides specialists in nuclear technology with sufficient grounding in chemistry to enable them to absorb completely the disciplines basic to their field.

The book reviews the elementary chemical fundamentals with nuclear applications, the essentials of radioactivity, nuclear reactions, and radio-chemistry, before covering the technological chemistry of nuclear materials.

A reference work for final year or graduate level students in nuclear science and engineering, this book contains a wealth of tables and data calculated to make it of the greatest interest and value to the practising nuclear technologist.

Contents include: General chemical fundamentals; The fission products; Uranium solution chemistry; Recovery of uranium and thorium from ores; Processing of irradiated reactor fuels; Isotope separation; Fluid reactor fuels; Chemistry of reactor materials.

384 pages Well illustrated **94s. net ($12.50)**

dissipate during rest, thus giving rise to the so-called 'reminiscence' phenomenon, that is, an improvement of performance during rest, as indexed by subtracting performance at the end of the pre-rest period from that at the beginning of the post-rest period. Thirdly, it is deduced from the theory that the growth of inhibition should ultimately lead to the cessation of activity, that is, the occurrence of certain blocks or involuntary rest pauses. All these consequences have frequently been observed, as have others more in the perceptual field such as the so-called 'figural after-effect'.

I have suggested a link between personality and the theory of excitation and inhibition by postulating that extroverts are characterized by the particularly rapid rise of cortical inhibition, its slow dissipation, and its relatively high level. Conversely, introverts are characterized by the slow growth, rapid dissipation and generally low level of cortical inhibition. The opposite prediction is made with respect to excitation, that is, introverts show a high degree of excitation, extroverts a low degree. (It will, of course, be realized that we are talking about cortical inhibition and excitation, not about inhibited or excited behaviour. Cortical inhibition, by depressing the activity of the highest centres, may give rise to uninhibited behaviour[3].)

Proof for a theory of this kind would, of course, be sought in examining the behaviour of behaviourally extroverted and introverted subjects on laboratory tests of massed and spaced practice, reminiscence, amount of 'blocking', length of figural after-effects, etc. Much evidence has been accumulated in recent years to show that the predicted effects do, indeed, differentiate extroverts and introverts in the predicted direction. Technically much of this work is quite complex, as it is often difficult to rule out irrelevant factors which interfere with the pure measurement of the effects in question. Nevertheless, there seems to be little doubt at the moment that in its broad outlines the theory is supported by the experimental facts amassed so far.

Fig. 2 gives a systematic picture of the hypothetical relations between the genotypic level we have been discussing hitherto, and the phenotypic level of extroverted and introverted behaviour. It will be seen that we postu-

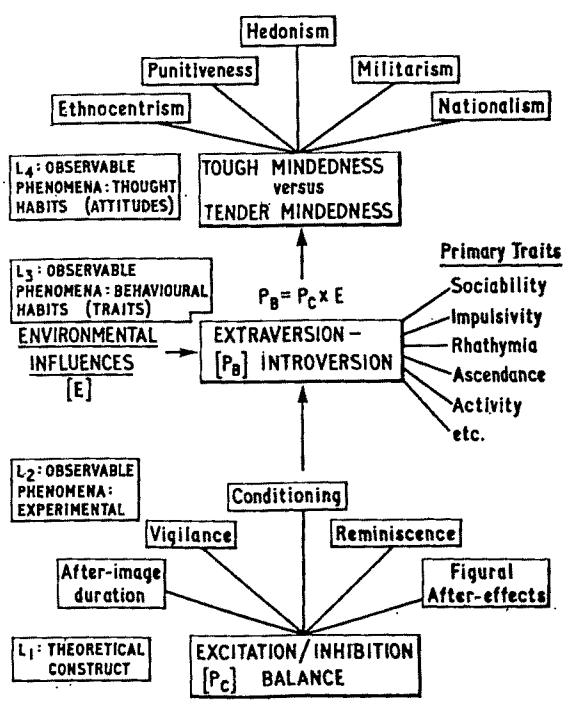

Fig. 2. Diagram illustrating relationship between genotype and phenotype in the personality field (ref. 8)

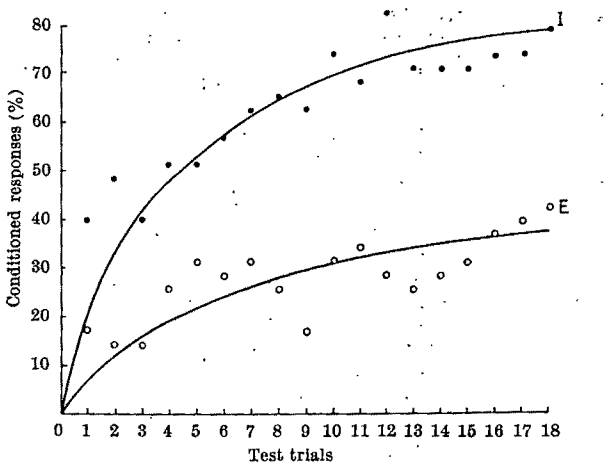

Fig. 3. Rate of eyeblink conditioning in groups of introverted and extroverted subjects (ref. 9)

late several different levels, going from the hypothetical excitation–inhibition balance at the bottom, which we considered to be the physiological basis of our constitutional personality (P_C), to the higher levels of behavioural personality (P_B), which is a product of constitution and environment, and which manifests itself in the form of behavioural habits or traits such as sociability, impulsivity, ascendance, etc., or in terms of thought habits or attitudes. (There is an empirical relationship between tough-minded attitudes and extroverted behaviour patterns.)

The relationship between levels 2 and 3, that is, observable, experimental phenomena, and the observable, behavioural phenomena, is a very complex one which will undoubtedly repay intensive study. We can only discuss here very briefly one particular link as an illustration of the type of argument and empirical demonstration which requires to be adduced. It will be noted that among the laboratory phenomena at the second level I have listed Pavlovian conditioning; the hypothesis states that the process of conditioning produces inhibitory potentials, that it does so more strongly in the extrovert than in the introvert, and that consequently introverts should condition better than extroverts. Fig. 3 shows the results of some experiments in which introverted and extroverted subjects were given the eyeblink conditioning test in which a sound delivered over earphones constitutes the conditioned stimulus and a puff of air to the cornea of the eye the unconditioned stimulus, producing closure of the eyelid. It will be seen that the hypothesis is supported by the data, introverts showing about twice as high a level of conditioning as do extroverts.

Modern learning theorists have hypothesized that neurotic symptoms, such as phobias, anxieties, obsessional and compulsive behaviour patterns, etc., are nothing more than conditioned autonomic and skeletal responses, and that they can be extinguished according to the rules which govern the extinction of such conditioned responses in the laboratory; there is much empirical support for such a contention. Now it will be clear that such conditioned responses are more likely to occur in individuals predisposed to the development of conditioned responses by the possession of a central nervous system which conditions easily. Thus we would expect, on the basis of these theories, that neurotics of this type would be introverted from the descriptive point of view, and would also condition extremely well. There is much impressive evidence to support both these deductions[4,5].

It has also been argued that the process of socialization, by means of which the young child learns the mores of his society, is mediated by Pavlovian conditioning, and it would seem to follow that psychopaths ('moral imbeciles'), and criminals generally, should be found largely

among persons who are extroverted and who condition poorly. (The argument is, of course, exactly the opposite to that which applies to the neurotics discussed in the previous paragraph.) The evidence is indeed very strong that persons in these groups are extroverted and there are several investigations which show that they condition very poorly, if at all. Pavlovian conditioning, therefore, seems to provide an efficient bridge between our level 1, that of the theoretical construct of the excitation–inhibition balance, and level 3, that of observable behavioural phenomena.

Is it possible to locate any structure within the nervous system which may be responsible for individual differences in these mysterious processes of excitation and inhibition ? I would suggest that the ascending reticular formation may fit this prescription reasonably well. This formation, which is located on the spinal cord from the brain stem through the mid-brain to the diencephalon, provides an alternative pathway for ascending impulses proceeding from the periphery to the cortex, impulses travelling along the classical afferent pathways entering the reticular formation via collaterals from the afferent, and giving rise to impulses that are not only directed to the primary cortical projection area but may also be projected profusely over a wide area of the cerebral cortex. Parts of the formation (the so-called ascending reticular activating system) are known to be involved in cortical facilitation; they thus fit in with the psychological concept of 'excitatory potential', while the so-called 'recruiting system' acts as a suppressor and thus has affinities with the psychological concept, 'inhibitory potential'.

Evidence for this identification is largely indirect, the strongest argument in favour being perhaps that deriving from the action of stimulant and depressant drugs. These are known to shift a person's position on the extroversion–introversion dimension in the direction of greater introversion (stimulant drugs) or in that of greater extroversion (depressant drugs), and it is known that these drugs on the whole tend to act through the ascending reticular formation[6]. This hypothesis linking psychological concepts with physiological structures is offered only very hesitantly; it will undoubtedly require much modification before being found acceptable. However, it does serve to unify several quite distinct lines of research and may, in turn, give rise to experimental studies likely to clarify the issue and to reveal to us more directly some of the biological roots of personality.

A THEORY OF CROSSING-OVER BY MEANS OF HYBRID DEOXYRIBONUCLEIC ACID

By Dr. H. L. K. WHITEHOUSE
Botany School, University of Cambridge

THE term 'crossing-over' was introduced into genetical literature by Morgan in 1912 to describe the phenomenon he had discovered whereby new combinations of linked characters arose. Several theories to explain the process have been put forward in the intervening half-century. Ideas suffered a radical change in 1955 when the classical theory of reciprocal recombination was overthrown. This followed acceptance of the notion that, within small segments of the hereditary material, the products of recombination are not always complementary. Lindegren[1] had first suggested this on the basis of his work with *Saccharomyces cerevisiae*; but the idea did not gain wide support until Mitchell[2] demonstrated the phenomenon in *Neurospora crassa*. One of the first examples of non-reciprocal recombination which she found was remarkable in that conversion (as the non-reciprocal process is often called) had taken place in opposite directions at allelic sites.

In attempting to formulate a general theory of the mechanism of recombination, a difficulty has been the diversity in the results obtained with different organisms. In *Aspergillus nidulans*, where in ordinary linkage studies there appears (unlike *Neurospora*) to be no interference between cross-overs, Pritchard[3] found it necessary to postulate the frequent occurrence of more than one cross-over in short segments, which he called regions of 'effective' pairing, while non-reciprocal recombination has been somewhat rarely recorded[4]. In *Ascobolus immersus*, on the other hand, Lissouba and Rizet[5] and Lissouba *et al.*[6] have shown that non-reciprocal phenomena occur regularly at loci concerned with spore pigmentation, and moreover that a polarity is evident in the data. Within a group of apparently linearly sited alleles, if one is found to show conversion more frequently than another placed to the left of it, then the right-hand member of any other pair of them is found to show a similar difference from the left-hand member. Such polarity has not been demonstrated in *Neurospora*.

Variability is also shown within species. In *Neurospora*, Lindegren and Lindegren[7] found a significant excess of two-strand double cross-overs across the centromere of one of the linkage groups, while others (for example, Stadler[8]) have found no such chromatid interference. In *Ascobolus*, Lissouba *et al.*[6] have found that within a series of multiple alleles different pairs may show diversity in the relative frequencies of occurrence of reciprocal and non-reciprocal recombination.

Copy-choice Hypothesis

The hypothesis that has most frequently been used to explain non-reciprocal recombination is the theory of 'switch synthesis' or 'copy-choice', which relates recombination to replication of the hereditary material. This hypothesis requires that homologous chromosomes shall be paired, at least at certain points along their length, at the time of replication and that the new strands may be replicas of one parental strand in one region and of the other one in another region (Fig. 1). This idea provides a neat explanation of how within a tetrad one site may show a 2 : 2 ratio and a neighbouring one a 3 : 1 ratio.

The theory has been extended by Lissouba *et al.*[6] to take account of their observations on polarity, by postulating that the direction in which replication occurs is from left to right, that is, towards sites with the higher conversion frequency, and, furthermore, that once a copying 'error' has been started it continues to the end of the group of sites. They have coined the term 'polaron' for such a group of sites within which crossing-over appears to be absent.

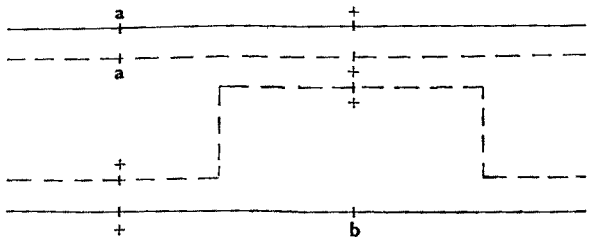

Fig. 1. Diagram to illustrate the copy-choice hypothesis. Old chromatids are shown by unbroken lines, and newly synthesized chromatids by broken lines; *a* and *b* represent the sites of allelic mutations, and the + signs their normal counterparts

The copy-choice theory, and its extension in the polaron concept, are open to a number of serious criticisms:

(1) The theory of the polaron, as proposed by Lissouba *et al.*[6], demands that few or none of the copying errors should continue through the intervening so-called 'linkage structure' to the next polaron, yet Stadler[9] has shown that, according to Lissouba's own data, a majority do so.

(2) Watson and Crick[10] postulated that the method of replication of deoxyribonucleic acid (DNA) was such that each new DNA molecule contained one of the nucleotide chains from the parent molecule and one new one. The work of Meselson and Stahl[11] showed that DNA replication in *Escherichia coli* followed the Watson and Crick method, and these observations were extended to a chromosomal organism, *Chlamydomonas reinhardi*, by Sueoka[12]. Taylor[13] showed that the chromosomes in root-tips of various flowering plants replicated by the same method, so far as their DNA was concerned. These observations suggest that the terms 'old' and 'new' must be applied, not to the two daughter-chromatids from one chromosome, but rather to half of each DNA molecule within them. On the other hand, the idea of copy-choice implies the contrary, namely, that replication is at the chromatid and not the sub-chromatid level.

(3) Meselson and Weigle[14] and Kellenberger *et al.*[15] showed that in lamba phage of *Escherichia coli*, genetic recombination can occur in the absence of replication of DNA.

(4) The necessity, on the copy-choice theory, to associate conversion with replication of DNA presents difficulties, since replication appears to occur at the end of the resting-stage prior to meiosis, before homologous chromosomes are thought to have associated[16]. Furthermore, if reciprocal recombination (crossing-over) also occurs at the time of DNA replication, then it is presumably necessary to postulate that chiasmata must already exist at the earliest stages of meiosis, though not observed. Alternatively, if crossing-over is thought to occur at the pachytene stage, as generally supposed, then a mechanism is required to associate the places of occurrence of reciprocal and non-reciprocal recombination in each meiosis. For it is evident from tetrad analyses in *Neurospora crassa*, such as those by Case and Giles[17], that about half the conversions were associated with crossing-over of 'marker' genes on either side of the pair of alleles. Yet the marker genes were so closely linked that they would have been expected to remain in their parental combinations in more than 90 per cent of instances if the two phenomena had been independent of one another. Earlier work[18,19] in which prototrophs at a nutritional locus were selected among random ascospores from crosses between alleles, had pointed to the same conclusion. Thus, if non-reciprocal and reciprocal recombination are thought to occur at different times, it is necessary to associate them, for example, by postulating that they occur in the same effective pairing segments.

In view of these difficulties and contrary evidence, and above all on account of the fundamental dilemma presented by the occurrence of DNA replication at the sub-chromatid level, the copy-choice theory must in my opinion be discarded as an explanation of genetic recombination between chromatids at meiosis.

Search for an Alternative Theory

In looking for an alternative to the copy-choice theory, one feature of conversion which appears highly significant is the association between it and crossing-over. Not only are the two phenomena often associated in position, as indicated here, but they also appear to be associated as regards the strands involved. Data from the analysis of tetrads in *Neurospora crassa* are given in Table 1. The early results obtained by Mitchell[2] and by Case and Giles[17] had indicated that, when reciprocal and non-reciprocal recombination occur in proximity, two strands might be participating more often than three, although the difference was scarcely significant. However, additional data obtained in this laboratory by Threlkeld[21] and by Cooke[22] make it appear certain that this excess is real. This conclusion is confirmed by the extensive data, not yet published, of Stadler and Towe[23]. Indeed, on the basis of the total data, three chromatids appear to participate so rarely (6 instances out of 42) as to suggest that a third strand may be involved only when the cross-over concerned is not in fact in the immediate vicinity of the non-reciprocal event.

The data of Kitani *et al.*[24] on the segregation of marker genes on either side of the locus for grey *versus* normal black spores in *Sordaria fimicola* point to the same conclusion. Out of 11 asci showing a 6 : 2 ratio of spore colours, and also showing recombination of marker genes on either side, the frequencies of those involving 2 and 3 strands were 9 and 2, respectively. Similarly, out of 52 asci showing 5 : 3 ratios and marker recombination, the 2- and 3-strand frequencies were 48 and 4, respectively. The markers spanned about 4 units of the linkage map.

In searching for an alternative to copy-choice as an explanation of non-reciprocal recombination, it was also evident that some replication of DNA must be postulated, in addition to the doubling which occurs just before meiosis. The occurrence within a tetrad of 3 : 1 ratios at a mutational site demands that such additional replication shall have taken place. Since there is clearly some connexion, from the evidence given here, between crossing-over and conversion, it would be reasonable to suggest that short segments of the DNA of a chromatid may undergo an extra replication at about the same time as crossing-over occurs. This would presumably be at the zygotene or pachytene stage. Was it possible that such further replication could occur in the process of crossing-over itself ?

Theory of Crossing-Over by Molecular Hybridization

It has been customary to regard crossing-over as a process of breakage of two chromatids at corresponding points, followed by rejoining the other way round. As applied to two DNA molecules, this would mean breakage of internucleotidic links in each pair of nucleotide chains

Table 1. THE FREQUENCIES WITH WHICH TWO AND THREE CHROMATIDS TAKE PART WHEN RECIPROCAL AND NON-RECIPROCAL RECOMBINATION OCCUR IN PROXIMITY IN *Neurospora crassa*

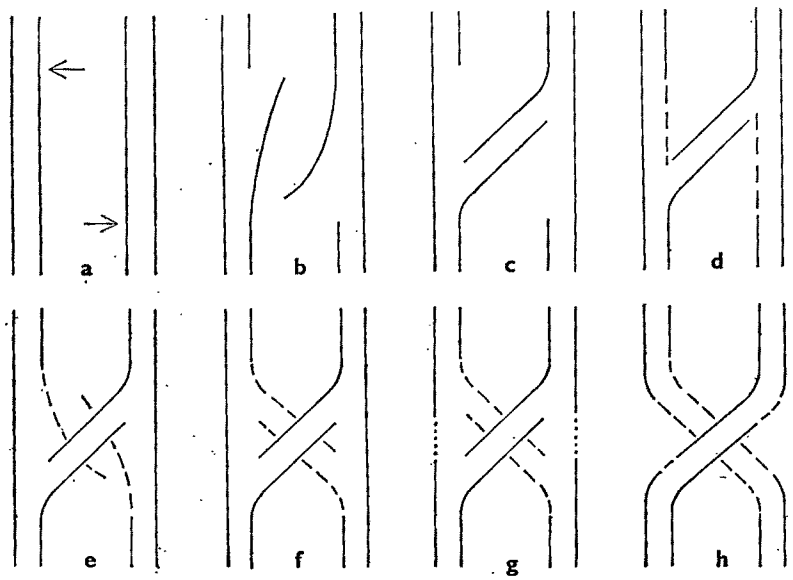

Fig. 2. Hypothetical stages in the process of crossing-over between two DNA molecules, according to the first model, in which the initial points of breakage (arrows) are non-homologous. Old nucleotide chains are shown by unbroken lines, newly synthesized chains by broken lines, and chains which are breaking down by dotted lines. No attempt has been made to show the spiral coiling

in each molecule, followed by re-establishment of the links with new partners. Such behaviour is out of keeping with the known peculiarities of the molecule, of which the most remarkable is the complementary base-pairing between the two nucleotide chains. Was it possible to explain crossing-over by means of this base pairing ?

If both chromatids were broken at precisely corresponding places, crossing-over by base-pairing would appear to be impossible (but see following). On the other hand, if the breaks were at not quite identical places, and involved one nucleotide chain from one molecule and the complementary chain from the other, then the two longer broken ends would have terminal portions which overlapped and hence were complementary to one another. Base-pairing would thus be possible between them, giving rise to one of the cross-over DNA molecules. The reciprocal cross-over molecule could not, however, be formed in the same way, because the other two broken ends would necessarily both be deficient for the segment which the longer broken ends had in common. It was evident that to construct the reciprocal cross-over molecule some replication of DNA was required. Such replication was just what was needed to explain non-reciprocal recombination, and so the possibility was opened of explaining both kinds of recombination by a common mechanism.

On the hypothesis now proposed, broken ends of nucleotide chains of DNA do not join terminally, but instead all reconstruction is by lateral association of chains through complementary base-pairing. Two ways of bringing about crossing-over then appear possible.

First Model

The steps in crossing-over would be as follows:

(1) Complementary nucleotide chains, one from each DNA molecule, break at nearly but not exactly homologous points (Fig. 2*a*).

(2) The parts of the two broken chains between the two breakage points uncoil from their complementary chains (Fig. 2*b*), and then coil round each other so that complementary base-pairing occurs between their terminal portions to form a cross-over molecule (Fig. 2*c*).

(3) New nucleotide chains are synthesized alongside the old chains that have not crossed over (Fig. 2*d*).

(4) The new chains uncoil from their complements, peel back (Fig. 2*e*) and unite by complementary base-pairing to form the other cross-over molecule (Fig. 2*f*).

(5) The old nucleotide chains that have not crossed over break down (Fig. 2*g*) and complementary nucleotides fill the gaps in the two cross-over molecules (Fig. 2*h*).

The detailed consequences of crossing-over, if it occurred by this means, are shown in Fig. 3, where the individual nucleotides are indicated by the letters of the alphabet, capitals (*A*, *B*, *C*, *D* . . .) for those contributed by one parent, and lower case (*a*, *b*, *c*, *d* . . .) for those from the other. (There are, of course, only 4 different nucleotides, but the whole alphabet is required in order to define a sufficient length of the unique sequence of them.) The situation in Fig. 3 (i) corresponds to that in Fig. 2*e*, where the first cross-over molecule has formed and the second one is about to do so. The end-products of the cross-over are shown in Fig. 3 (ii). Both cross-over molecules necessarily have a segment of the DNA in which one nucleotide chain is derived from each parent. The question of whether such DNA is heterozygous or homozygous is discussed later. The expression 'hybrid DNA' as used here is intended merely to imply that it is of dual parentage. The ends of the first-formed hybrid segment (*G–T* in the diagram) are determined by the positions of the initial breakages, while those of the second one (*H–Q* in the diagram) are determined by the points where the formation of the two new chains ceased. Thus, as in the example illustrated, the hybrid regions in the two molecules need not correspond and, moreover, might be expected to vary in length and relative position from one cross-over to another. An important consequence of the theory is evident, namely, that a cross-over does not occur between specific nucleotides of the two DNA molecules,

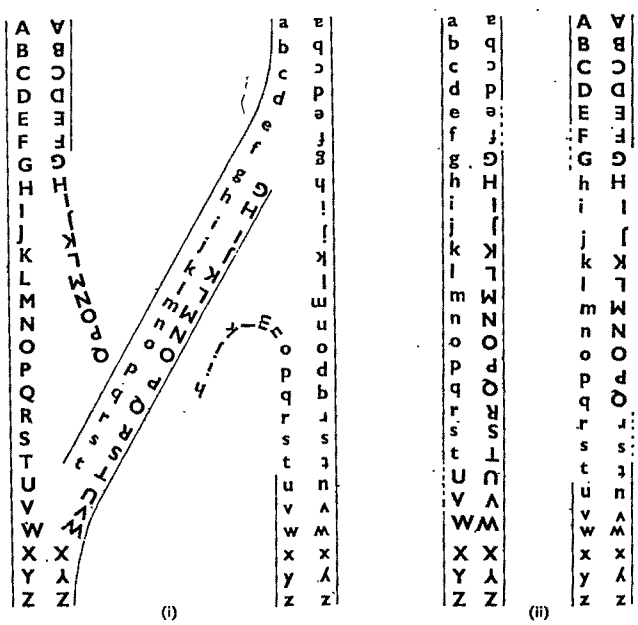

Fig. 3. Stages in the process of crossing-over, according to the first model. The unique sequence of nucleotides is indicated by the letters of the alphabet (although there are, of course, only four different nucleotides), and the parentage by capitals and lower case, respectively. Inverted polarity in the chains is shown by inverting the letters. An unbroken line alongside the lettering indicates old nucleotide chains, the absence of a line implies a new chain synthesized during crossing-over, and broken lines show chains which might be either old or new. No attempt has been made to show the spiral coiling. (i) Stage of crossing-over shown in Fig. 2 (*e*); (ii) end-products of the cross-over

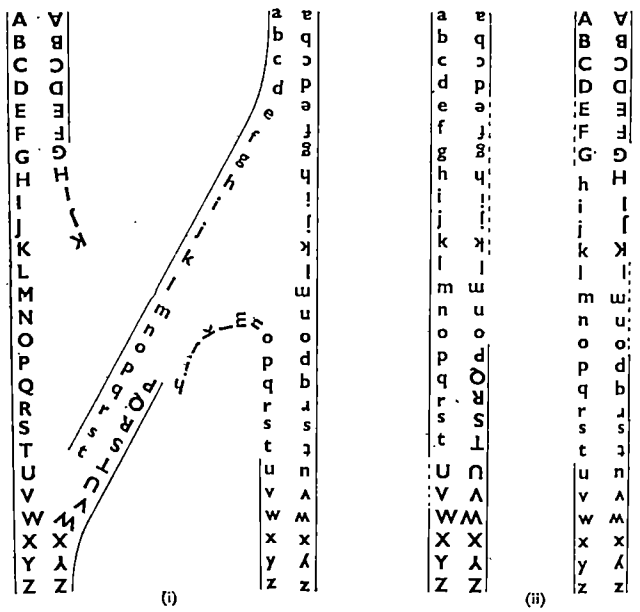

Fig. 4. Stages in the process of crossing-over, according to the first model, corresponding to those in Fig. 3, to show how loss of primary segment *G–O* and secondary segment *L–Q* will cause non-reciprocal recombination (conversion) at sites *L–O*

but instead occupies a significant length of the nucleotide chains, and therefore has a number of mutational sites lying within it.

The account of crossing-over just given does not explain non-reciprocal recombination, but the occurrence of additional replication of DNA gives to the mechanism the potentiality of doing so. A slight modification to the steps outlined here will suffice to bring it about. This alteration is illustrated in Fig. 4, where stages are shown corresponding to those in Fig. 3. The essential difference is that certain nucleotides are missing from the contribution to the cross-over by one parent. Such loss could no doubt readily occur as a result of breakage of one or other or both of the segments of the chain when necessarily unpaired prior to formation of the cross-over molecules. In Fig. 4 (i), as compared with Fig. 3 (i), losses are shown in both segments contributed by one parent, *G–O* from the primary chain and *L–Q* from the secondary one, giving a deficiency for nucleotides *L–O*. After formation of the cross-over molecules, the gaps caused by this deletion can only be filled by nucleotides complementary to those in the other chain, with the result that both cross-over chromatids will have this segment derived from the same parent (Fig. 4 (ii)). This implies that non-reciprocal recombination has taken place over this region. As can be seen from the diagram, the converted segment (*l–o*) lies between the two regions of hybrid DNA (*P–T* in the primary cross-over molecule and *H–K* in the secondary one). The direction in which conversion takes place will depend on which parental molecule suffers the deletion of a segment from the chain that is about to cross over.

Second Model

It was suggested earlier that if the initial breaks were in corresponding positions instead of being staggered, there would be no opportunity for complementary base-pairing, and hence for crossing-over. However, if, following such breakage, the nucleotide chains separated in one direction from the points of breakage, as in Fig. 5 (*b* or *n*), chain synthesis could occur alongside the unbroken chains (Fig. 5. *c* or *o*), and cross-over molecules could arise by base-pairing between the complementary old and new broken chains (Fig. 5, *d* and *e*, or *p* and *q*). Breakdown of the parental previously unbroken chains would complete the process of crossing-over (Fig. 5, *f* and *g*, or *r* and *s*).

In the first model, one cross-over molecule was constructed from the two old chains and the other from the two new ones, and so their formation was likely to be sequential. In the present scheme, the formation of the cross-over molecules could be simultaneous, as each has one old and one new chain. As with the first model, loss of segments from the two free ends of the chains belonging to one parent, such as to leave this parent's contribution to the cross-over deficient for one or more nucleotides, will automatically lead to a corresponding converted segment in the middle of the cross-over.

On this second model, crossing-over could occur in the manner outlined, provided the nucleotide chains unwound in one direction only from the point of breakage, that is, either upwards (Figs. 5, *b–g*) or downwards (Fig. 5, *n–s*). If they separated in both directions, a remarkable situation would develop, illustrated in Fig. 5, *h–m*. Chain synthesis could occur alongside the unbroken chains (Fig. 5, *i*), but the new chains could not become attached at either end because of the old ones. If they separated from their unbroken complements, they could pair with the broken chains, provided they changed sides as in Fig. 5, *j*, *k*. The consequence of this, if the process followed a similar course to that outlined here for crossing-over, would be to produce hybrid DNA in both molecules, but no cross-over (Fig. 5 *l*, *m*).

The detailed effects of this process of nucleotide exchange are shown in Fig. 6, where diagram (i) corresponds to the stage reached in Fig. 5 *k*. The secondary chains have changed sides, and the pairing with their complementary broken primary chains is almost complete. In Fig. 6 (ii), the end-products of the process are shown, the molecules being hybrid from *E* to *R* and from *I* to *V*, respectively. The process that has taken place is effectively one of exchange of a segment between one nucleotide chain of each of two DNA molecules, but with the provision that the exchanged parts need not be exactly the same as regards their length and position in the molecules.

The effects will now be considered of loss of terminal segments from one or more of the four primary free ends in the configuration under discussion. If the lost part of a chain is long enough to give a deficiency in that parent's contribution to the process of exchange, conversion will result. In Fig. 6 (iii) it has been supposed that primary segment *G–M* of Fig. 6 (i) had been lost, thereby shortening this arm to a point beyond the end of the secondary chain (*I–V*) of the same parentage. In consequence, sites *G* and *H* show conversion to the other parent. In this diagram it has also been imagined that primary segment *n–t* has been lost, and since the secondary chain of this parentage ends at site *r*, conversion to the other parent will occur at sites *s* and *t*. It is evident that losses of the kind indicated, that is, from a primary chain and extending beyond the end of the secondary chain of the same parentage, will produce conversion without crossing-over. In general, they may cause conversion in either direction in either or both of two nearly adjacent regions. In any particular instance, the interval between these regions will be determined by the distance between the appropriate ends of the secondary chains (*I* to *r* in the example given).

Fig. 6 (iii) also illustrates an even more remarkable possibility. It is supposed that primary segment *k–m* has been lost. In conjunction with the loss of the homologous primary segment derived from the other parent (that is, *K–M*), this will give rise to reciprocal conversion, that is, a two-strand double cross-over in a short interval, sites *K–M* being exchanged between the two parents. Since this end-result merely requires loss of homologous segments, however short, from the primary chains, it can occur in the absence of conversion, which, as indicated

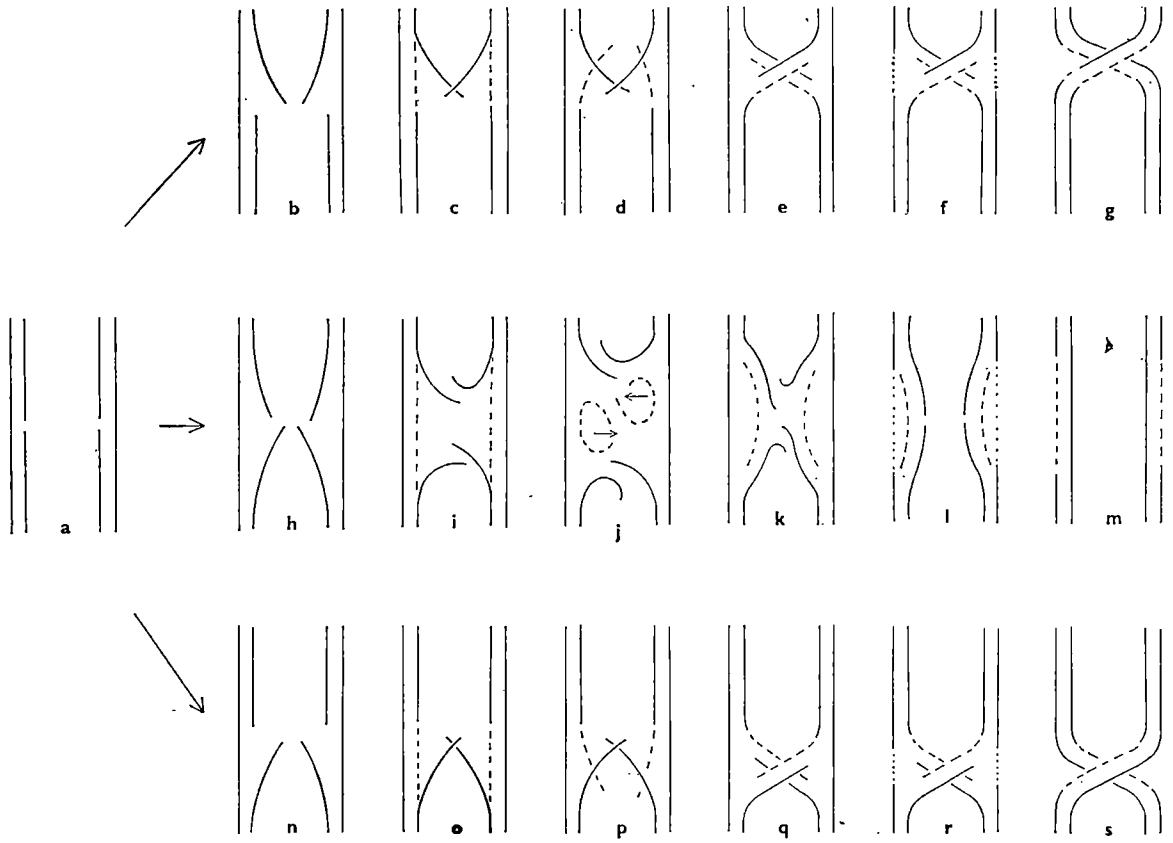

Fig. 5. Hypothetical stages in the processes of crossing-over and of nucleotide-chain exchange, according to the second model in which the initial points of breakage are homologous. Old nucleotide chains are shown by unbroken lines, newly synthesized chains by broken lines, and chains which are breaking down by dotted lines. No attempt has been made to show the spiral coiling. Diagram (*a*) shows the initial breakage; diagrams (*b*)–(*g*) show stages of crossing-over when the upper chains separate from their complementary chains; (*h*)–(*m*) the stages of nucleotide chain exchange when both upper and lower chains separate; and (*n*)–(*s*) the stages of crossing-over when only the lower ones separate

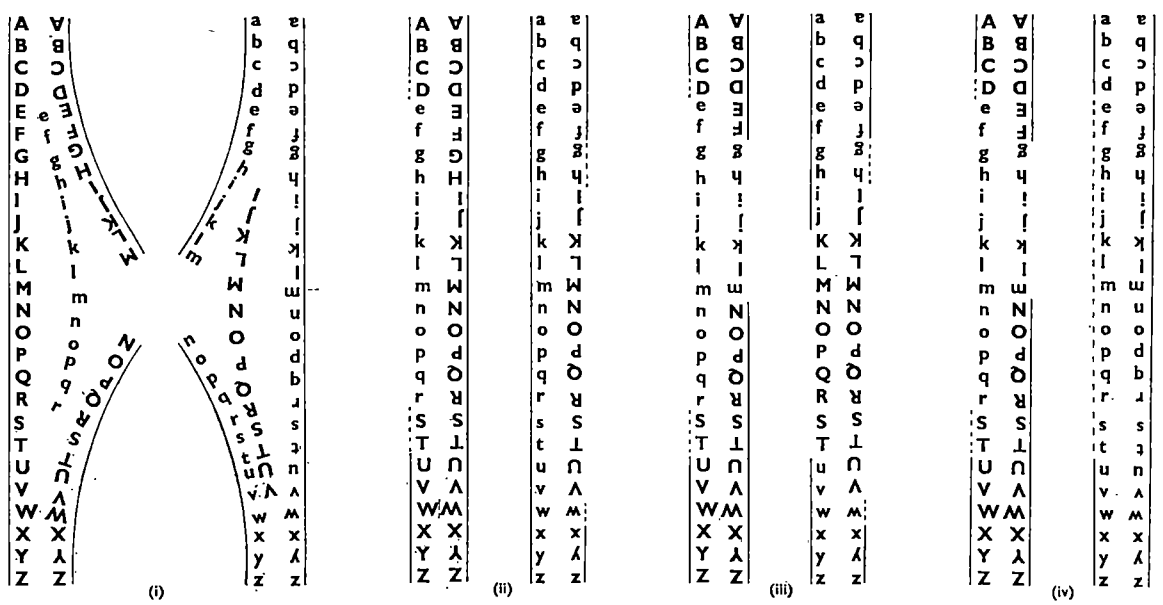

Fig. 6. Diagrams to illustrate the process of nucleotide chain exchange. The significance of the lettering and lines is the same as in Figs. 3 and 4. (i) Stage of nucleotide exchange shown in Fig. 5 (*k*); (ii) end-products of the exchange process; (iii) end-products if primary segments *G*–*M*, *k*–*m* and *n*–*t* have been lost; sites *G* and *H* show conversion in one direction, and *S* and *T* in the opposite direction; sites *K*–*M* show a reciprocal conversion, that is, they are spanned by a two-strand double cross-over; (iv) end-products if primary segment *G*–*M* and the entire secondary chain (*I*–*V*) have been lost; sites *G*–*M* show conversion

here, requires the lost segments to be long enough to extend beyond the end of the secondary segments.

Another variation which might be expected to occur, arising from this configuration with the four primary free ends, is the result of a failure of one of the secondary chains to be formed, or having formed, to pair with its complementary broken primary chain from the other molecule. Such failure would lead to hybrid DNA in one molecule, but to parental DNA in the other. Loss of a segment, however small, from either of the primary broken ends belonging to the parent which failed to produce a secondary chain will then cause conversion. This is illustrated in Fig. 6 (iv), where it has been supposed that one of the secondary chains (*I–V* in Fig. 6 (i)) failed to develop. It has further been supposed that primary segment *G–M* has been lost, with the result that these sites show conversion.

If the initial breakage-points were at homologous positions in similar instead of complementary nucleotide chains of the two DNA molecules, no exchange of material would be possible, unless segments from one molecule broke off and became directly incorporated, without replication, in the other. On the other hand, if the breakage-points were non-homologous, as in the first model of crossing-over, and if the chains unwound in both directions from the points of breakage, then conversion without crossing-over would be possible. It would be necessary for a secondary chain to form against one of the longer broken arms, and then for this chain to become detached and pair with the broken chain of the other molecule, and to span the gap between its two broken ends. This would give hybrid DNA in one molecule, and if the tip of one of the broken chains had been lost, conversion would occur. The reciprocal process could also take place, thereby giving rise to conversion in opposite directions in neighbouring but not quite adjacent regions. On the other hand, reciprocal conversion (a two-strand double cross-over) could be generated only by making the improbable assumption that both the longer arms lost segments of particular lengths while they were exchanging secondary chains.

To sum up, the first model (with non-homologous points of breakage) appears able to account for crossing-over with and without conversion, but in order to explain conversion without crossing-over, it is necessary to postulate that similar instead of complementary chains were broken in the two DNA molecules. On the other hand, the second model (with homologous breakage-points) will account for all three possibilities as the result of complementary strand breakage. This model also predicts the occurrence of two-strand double cross-overs in short intervals, which are unlikely on the first model.

Hybrid DNA

A fundamental feature of the theory of crossing-over that has been proposed here is the occurrence of hybrid DNA in the region of cross-overs or potential cross-overs. Heterozygous DNA would imply segregation of genetic differences at the first mitoses after meiosis, and such an occurrence, although known, is quite rare. It is presumed, therefore, that the hybrid DNA, although often potentially heterozygous, usually becomes homozygous in the process of formation of the hybrid molecules. This could be achieved by the removal from one chain at each heterozygous site or region of those nucleotides which did not conform to those in the other chain, followed by the insertion of nucleotides complementary to those in the first chain. At any particular site of heterozygosity it is to be expected that the two ways of making it homozygous (such as changing *Aa* to *AA* or to *aa*) will not necessarily occur with equal frequency. Indeed, the relative frequencies of the two alternatives might be expected to depend on the nature of the heterozygosity itself, that is, on whether the mutation is a nucleotide substitution or a minute structural change such as a deficiency or a duplication.

This process of replacement of the nucleotide sequence peculiar to one parent by that of the other may lead to non-reciprocal recombination, in the same way as does loss of segments from the primary broken chains. Whether or not conversion is manifest will depend on the direction of the change from the heterozygous to the homozygous condition, and on what has happened at this site in the other molecule. If both molecules contain hybrid DNA, there are four possibilities: if nucleotide replacement occurs in the same direction in both molecules, conversion will also take place in that direction (to *A* or to *a*). If the replacements are in opposite directions, either the parental condition will be restored or a reciprocal conversion (two-strand double cross-over) will have been produced spanning the site.

There would thus appear to be two ways in which conversion can take place: first, by a failure of one parent to contribute to the formation of potentially heterozygous DNA, and secondly, by nucleotide replacement in such DNA so as to make it homozygous. The frequency of occurrence of conversion by the first method will depend on the frequency of loss of the appropriate segments, and by the second method on the frequencies of nucleotide substitution in the two directions. The relative importance of the two methods can be established only from experimental data. It may be that the nucleotide substitution, whereby the DNA is rendered homozygous, is the method by which conversion is usually brought about, even though the alternative, namely, loss of particular segments of the primary broken chains, would automatically cause conversion.

Discussion

Detailed examination of the data on aberrant tetrads in *Neurospora crassa*, *Aspergillus nidulans*, *Sordaria fimicola* and *Ascobolus immersus*, in the light of the present theory, has not yet been attempted. It should assist discrimination between the two models of crossing-over, and provide information about the behaviour of potentially heterozygous DNA. Thus, the observation by Kitani *et al.*[24] that, in *Sordaria* heterozygous at the grey spore site, asci with 6 : 2 ratios and others with 5 : 3 ratios for spore colour may occur in the same cross, is of particular interest and implies on the present theory that when the DNA is hybrid at this site, its heterozygosity is sometimes maintained through meiosis. It is evident that, on either model, the theory will explain the association, both in position and in strands, between conversion and crossing-over, and also the occurrence of either phenomenon in the absence of the other. It will also explain how two conversions can take place in proximity but in opposite directions, as first found by Mitchell[2] in *Neurospora*.

The observation that reciprocal and non-reciprocal recombination are affected differently by heat treatment[19] or ultra-violet light[25] is not unexpected on the present theory, since the two kinds of recombination, although related, are caused in different ways. On the postulated mechanism of crossing-over, although there is no net change in DNA content, inhibition of DNA synthesis at the appropriate time will prevent crossing-over. This suggests that the theory might be more readily tested by looking for suppression of crossing-over or chiasma formation, as a result of such inhibition, than by attempting to detect the DNA synthesis directly.

Explanation of the polarity of the *Ascobolus* conversion data of Lissouba *et al.*[6] would be facilitated if marker genes were available on either side of the sites of the spore pigment mutations. However, Hastings[26] has pointed out that the polarity could be explained by making the following two postulates:

(1) In any particular region of the chromosome, when crossing-over or potential crossing-over is about to occur,

either the process of homologous pairing of chromatids or the formation of hybrid DNA takes place progressively along the chromosome in a fixed direction, say, from right to left.

(2) With certain mutations, the formation of hybrid DNA often ceases immediately beyond (to the left) of their sites, presumably as a consequence of the heterozygosity, which is perhaps structural.

Conversion would thus occur less frequently at sites with heterozygosity to the right of them than when this region was homozygous, since the heterozygous site would shield a region to its left (which would often include the other site) by preventing hybridization of DNA, either directly or through inhibition of pairing of chromatids.

The second model described here, where two free ends give rise to crossing-over, and four to conversion without crossing-over, suggests an explanation for the phenomenon of interference in the position of neighbouring cross-overs. As is evident from Fig. 5, both the crossing-over and the conversion have a common starting-point in the breakage at corresponding positions of complementary nucleotide chains from the two DNA molecules. It follows from this that the initial points of breakage might be randomly distributed, but the cross-overs show interference, if the effect of a cross-over was to divert neighbouring potential cross-overs into the other course leading to conversion.

Hastings[26] has suggested that the coiling of complementary nucleotide chains round one another, which is an essential part of the process of constructing the cross-over molecules, might itself lead to the uncoiling of the same chains at the next points of breakage and thereby favour diverting these cross-overs into the conversion path. If transmission of spiral torsion were the correct explanation of interference, the lack of it between cross-overs in opposite arms of a chromosome would imply that the DNA was not continuous from one arm to the other, or at least that the spiral torsion was not transmitted (cf. Darlington[27]). Conversely, the occurrence of interference throughout a chromosome arm would suggest that the DNA was continuous, in agreement with Taylor's observations[13]. That interference should exist within a chromosome arm, even when the cross-overs involve different chromatids, would presumably be a consequence of the pairing behaviour of chromosomes, such that only two chromatids participate in crossing-over in any particular region.

It is of interest that the occurrence of crossing-over and conversion in proximity and involving three strands altogether (Table 1) appears to happen more often than would two cross-overs in the same interval, implying that there is less interference (or perhaps none) between the places of occurrence of the two phenomena (cf. Stadler[28]). Moreover, in *Aspergillus*, where interference is absent, Strickland[4] found conversion to be comparatively rare, and his data are consistent with the view that conversion takes place only in conjunction with crossing-over. On the theory of interference suggested above, this would mean that, in *Aspergillus*, coiling of nucleotide chains round each other at one point fails to lead to their uncoiling at a neighbouring point.

The second model for crossing-over also offers an explanation for the excess of two-strand double cross-overs which Lindegren and Lindegren[7] found between genes placed on either side of the centromere of a *Neurospora* chromosome. Their results have sometimes been attributed to overlapping of the spindles at the second division of meiosis and not to crossing-over. However, analysis of their data (Whitehouse[29]) has shown that the cross-over phenomenon is real, and it has, moreover, been confirmed in this laboratory (Rifaat[30], Scott-Emuakpor[31]). A curious feature of these two-strand double cross-overs spanning the centromere is that they are frequently associated with an additional cross-over in the proximal region of either or both chromosome arms. On the present hypothesis of interference, if crossing-over is rare near the centromere, as is usual, conversion and its associated variant, reciprocal conversion, would be correspondingly frequent. If two mutant sites on either side of the centromere both fell in regions of reciprocal conversion in the same chromatids, provided there was no intervening cross-over, the result would appear as a two-strand double cross-over between the mutants, together with further cross-overs on either side, in agreement with observation.

Summary and Conclusions

It is suggested that crossing-over occurs by base-pairing between complementary nucleotide chains from two homologous DNA molecules. Two possibilities are discussed, depending on whether the initial breakage-points are homologous or not. Either model will account for non-reciprocal recombination (conversion), for its frequent association with crossing-over, and for such an apparent anomaly as double conversions in proximity but in opposite directions. An explanation for polarity in conversion frequencies is also offered. The second model (with homologous breakage) will explain, in addition, the phenomenon of interference between cross-overs, both as regards their position and the strands involved.

If the theory were accepted, the inference would be that the chromosome is single-stranded, in the sense that each gene is represented only once, and that the DNA is arranged longitudinally within it. The gulf that has existed hitherto between the study of heredity at the molecular and the chromosomal levels would then have been bridged.

I thank Mr. P. J. Hastings for invaluable discussion during the preparation of this paper, and for reading the manuscript. I also thank Mr. F. Cooke, Mr. M. B. Scott-Emuakpor and Dr. D. R. Stadler for permission to refer to their unpublished data, and Mr. G. J. Clark for assistance in the preparation of the diagrams.

NEWS and VIEWS

Mathematics at Royal Holloway College: Prof. F. R. Keogh

Dr. F. R. Keogh, senior lecturer in pure mathematics at the University College of Swansea, has been appointed to the newly created second chair of mathematics at Royal Holloway College, University of London. Dr. Keogh, who is forty years of age, worked at the Royal Aircraft Establishment, Farnborough, for six years before entering the University of Manchester as a student in 1947. He graduated in Manchester in 1950 and then spent three years at Emmanuel College, Cambridge, where he carried out research in analysis under the supervision of Dr. M. L. Cartwright, and later Prof. J. E. Littlewood. At Cambridge he gained a Ph.D. in 1954 and an Sc.D. in 1963. He has been a member of the staff of the Department of Pure Mathematics at Swansea since 1953 and was appointed senior lecturer in that Department in 1958. Dr. Keogh has published numerous articles on a wide field of classical mathematical analysis: univalent functions, Fourier series, and summability of sequences. His work is well known both from these publications and from the talks he has given at various colloquia and seminars. Analysts everywhere will welcome his appointment to this new chair.

Research at Unilever Ltd.: Dr. A. J. Kieran

Dr. A. J. Kieran retired on September 1 from his post in connexion with the administration of research in Unilever Ltd. After graduating at the University of Liverpool, Dr. Kieran joined Gossages, Widnes, an associate company of Unilever, as a research chemist in 1924. Five years later he became works manager of Gossages, and three years afterwards he was appointed to the position of works manager of Crosfields, Warrington. In 1938 he joined the headquarters staff of Unilever in London. During the Second World War, in addition to his work with Unilever, he was engaged on various Government assignments in the United Kingdom and North Africa. In 1945 he became a member of the South American Group Management which had just been established by Unilever. He returned to the United Kingdom, after a brief spell in the Philippines, in 1951, and took part with Dr. E. G. Woodroofe (now a vice-chairman, Unilever Ltd.) in the establishment of the newly created Unilever Research Division. Dr. Kieran is succeeded by Mr. A. C. Smith, who was previously information officer, Unilever Research Laboratory, Port Sunlight, Cheshire.

U.K. Advisory Council on Scientific Policy

The following four new members of the Advisory Council on Scientific Policy have been appointed for the period ending August 31, 1966: Prof. H. G. Callan, professor of natural history at St. Salvator's College, University of St. Andrews; Prof. A. H. Cottrell, Goldsmith's professor of metallurgy at the University of Cambridge and part-time member of the United Kingdom Atomic Energy Authority; Sir Ewart Jones, Waynflete professor of chemistry at the University of Oxford, member of the Council for Scientific and Industrial Research and Chairman of the latter Council's Research Grants Committee; Sir Patrick Linstead, rector of the Imperial College of Science and Technology and foreign secretary of the Royal Society. All four are Fellows of the Royal Society.

The Committee on Social Studies

It has been announced that the fields of interest of the Committee on Social Studies, set up under the chairmanship of Lord Heyworth (*Nature*, 199, 231; 1963), will include: economics, economic and social statistics, sociology, social psychology, social anthropology, and politics. In addition, the following fields include branches of social study which will concern the Committee: law—crime, organization of justice, etc.; medicine—social medicine, social psychiatry, etc.; geography—social and economic geography. Historical and international studies will present a special problem for the Committee. In general, it will concern itself with such research as is directly relevant to contemporary social and economic questions involving the United Kingdom. In considering the applications of research, the Committee will look for evidence in (*inter alia*) the following: government; administration (public, industrial, social and military); employment and industry; education; and the social services. Mr. A. B. Cherns (Department of Scientific and Industrial Research) has been appointed secretary to the Committee, and Mr. R. P. S. Hughes (Ministry of Health) assistant secretary.

Harwell Postgraduate Education Centre

The United Kingdom Atomic Energy Authority has decided to establish a Postgraduate Education Centre at the Atomic Energy Research Establishment, Harwell. This Centre will organize courses, outside the specialist area of reactor science, intended to further the education of the Authority's graduate staff. Some of these courses will be given by staff of the Atomic Energy Authority and may interest workers in allied fields outside the Authority. From time to time, therefore, such lecture courses as are arranged will be announced in *Atom*. The Reactor School, which has for many years given formal courses at graduate-level on reactor technologies, is now incorporated in the Postgraduate Education Centre. Its programme will continue along the same lines as before. Some of the Harwell research facilities have been made available to university Ph.D. students in the past and it is hoped that the Postgraduate Education Centre will be able to help in organizing such activities in future. Further information can be obtained from Mr. J. F. Hill, head of the Postgraduate Education Centre, Atomic Energy Research Establishment, Harwell, Didcot, Berks.

U.S. Naval Observatory 60-in. Astrometric Reflector

It is perhaps a little unusual nowadays to find a 60-in. telescope being constructed for astrometric purposes. However, it is very important that very faint stars should have their distances accurately known. A star may be faint for several reasons, two being that either the star is intrinsically bright but far away or intrinsically faint and nearby. It is to investigate this latter category of stars that this new telescope has been designed. Intrinsically faint stars—white dwarfs, red dwarfs and sub-dwarfs—are of fundamental importance for theories of stellar evolution. For such investigations it is necessary to know precisely how much energy is actually being radiated by the star and in order to determine this the distance of the star must be known. The 60-in. telescope has been designed for the measurement of the parallaxes of those stars in the group mentioned here which lie within 30 parsec of the Sun. The mirror is made of silica because of its low coefficient of thermal expansion and is paraboloidal of 15-m nominal focal length. The telescope will be mounted in a fork. The support of the mirror uses a compressed air system in place of the more usual system of levers. The telescope will be housed at the Flagstaff station of the U.S. Naval Observatory. The station is

2,300 m above sea-level and has excellent observing conditions. The new Observatory building has been designed to minimize the effects of high daytime temperatures, the whole building being insulated against the daytime rise in temperature (*App. Optics*, 2, 1; 1963).

Institute of Tropical Meteorology at Poona

An agreement has recently been made under which the United Nations, in collaboration with the World Meteorological Organization, will provide assistance for the establishment of an Institute of Tropical Meteorology at Poona. The object is to establish an Institute, as part of the Indian Meteorological Department, for carrying out investigations in applied meteorology. During the period of the International Indian Ocean Expedition, the Department will also establish a Special Division at Bombay to function as an International Meteorological Centre for co-ordinating and supporting the meteorological activities of the International Indian Ocean Expedition. At the conclusion of the activities of the Centre, the equipment and the relevant personnel will be transferred to Poona. The assistance of the United Nations Special Fund, through the World Meteorological Organization as the executing agency for the project, will continue for a period of three years. Seven experts will be provided for a total period of 15 man-years in the fields of forecasting techniques, tropical cyclone analysis and prognosis, use of machine methods in meteorological analysis and prognosis, climatology, hydrologic forecasting and meteorological research. There will be a chief expert for the project, appointed for a period of three years, who will also be the chief research forecaster in the International Meteorological Centre. On the side of the Government of India the Director-General of Observatories will have the overall responsibility for the execution of the project. Seven fellowships of one-year duration each will be awarded to technical personnel of the Indian Meteorological Department for advanced training abroad. Meteorological equipment, cloud and storm investigations equipment and an IBM 1620 electronic computor for data processing, calculating machines and photographic equipment and accessories will also be provided. In all, for this project, the Special Fund will contribute 873,500 dollars (U.S.) and the Indian Government about Rs. 50 lakhs.

Scientific Documentation in South and South-East Asia

Under the title *Scientific Documentation in South and South-East Asia*, the Unesco South Asia Science Co-operation Office, New Delhi, and the Indian National Scientific Documentation Centre, New Delhi, have published a survey of a regional seminar held at New Delhi during March 7–16, 1961, under the auspices of Unesco and the Government of India (Pp. iii+47. New Delhi: Unesco South Asia Science Co-operation Office; and Indian National Scientific Documentation Centre, 1963). It includes the inaugural addresses, a brief account of the organization of the seminar, a report on the position of scientific documentation in Asian countries (covering Burma, Ceylon, India, Indonesia, Japan, Malaya, Nepal, Pakistan, the Philippines, Singapore, Taiwan and Thailand), summaries of the technical papers presented, a note on co-operation, and a list of the proposals formulated for consideration. The last-mentioned include a request to be submitted by Unesco to the International Postal Union for reduced air-mail rates for scientific periodicals, expansion of the existing exchange between documentation centres of publications and photo-reproductions, establishment of an adequate network of microfilming units, and encouragement of the manufacture within the region of the simpler types of equipment for scientific documentation. The attention of governments is directed to the importance of developing, in each country, libraries with large collections of scientific literature as an essential basis for documentation services, and to the importance of Unesco Coupons for operating documentation services. The governments are also urged to make use of the facilities offered by the Unesco Technical Assistance and Participation Programmes and other aid programmes. Acceleration of the publication within the region of Union Catalogues, national lists of periodicals, and current National scientific bibliographies is also urged, and the importance of the exchange of scientific publications in developing scientific documentation generally is emphasized.

Recommendations for Letter Symbols, Signs and Abbreviations

Part 6 of the British Standards Institution's *Recommendations for Letter Symbols, Signs and Abbreviations* deals with *Electrical Science and Engineering* (*B.S.* 1991: Part 6: 1963. Pp. 52. London: British Standards Institution, 1963. 12*s.* 6*d.* net). The recommendations are listed under three sections which are entitled: "General Principles", "Specific Usages" and "Indexes". The first outlines the principles for use in scientific and technological work. These are intended, in particular, "for use in printed papers but they should be observed as far as possible in manuscript and typescript (with suitable instructions to the printer when necessary), and also by instructors in this work". This is all very well, but the section gives no indication to potential authors of how to signify to the printer details of case, type or font when writing by hand or using a normal typewriter—an essential aspect for consistency of style. "Specific Usages" lists quantities and their symbols, units and their symbols, and abbreviations: a Greek alphabet is appended. Section 3 is an alphabetical list of recommended symbols for physical quantities. An "Index of Words" is provided, also a short statement concerning the background, aims, objectives and organization of the British Standards Institution.

Inaugural Lectures at the Imperial College of Science and Technology

The acceptance of a chair in a university in Great Britain usually carries with it to-day the duty of the preparation and delivery of a public inaugural lecture at which the professor is formally introduced to the university and the wider public. Originally the inaugural lecture was merely the first lecture given by the professor in the ordinary course of his teaching duties. The text of the inaugural lecture is now printed and published. In addition, since the inaugural lectures at the Imperial College of Science and Technology, London, are all confined to science and technology, they can be combined in groups to be published in book form. The fourth volume in the series of *Inaugural Lectures* at Imperial College has recently been issued. It contains nine lectures covering the period of the two academic sessions 1960–61 and 1961–62. They are: K. G. Denbigh (chemical engineering science) on "The Science of Continuously Operating Systems"; H. Elliott (physics) on "Cosmic Rays and the Exploration of Space"; J. S. Rowlinson (chemical engineering) on "The Impact of Chemical Physics on Technology"; B. G. Neal (applied science with special reference to engineering) on "Some Problems in Plasticity"; B. J. Mason (cloud physics) on "The Physics of Clouds, Rain and Lightning"; M. H. Fleming (mineral technology) on "Mineral Technology—Progress and Problems"; J. H. Westcott (electrical engineering) on "A Prospect of Automatic Control"; W. D. Gill (oil technology) on "Geology in the Search of Oil"; and Sir Willis Jackson (electrical engineering) on "The Partnership between Science and Electrical Engineering".

Man the Tool Maker

Dr. Oakley is well known for his extensive research on Quaternary geology and early prehistory. His work lies

in the anthropological section of the British Museum (Natural History), South Kensington. *Man the Tool Maker* is a classic and first appeared as long ago as 1949. It is one of the best introductions to the subject of early prehistory yet published. Recently, a reprint has become available of the fifth edition which has been brought completely up to date (Pp. v+98+2 plates. London: British Museum (Natural History), 1963. 4*s*.). Many spectacular finds of earliest man have been made in East and South Africa and Dr. Oakley has visited not a few of the sites and checked the results claimed. Not only has it been necessary to be sure that the new finds are really *in situ*, but also their date, both in the geological sequence and their absolute age as determined by the carbon-14 method, has had to be settled beyond cavil. The first appearance of man has been pushed back into a far more remote past than had formerly been realized. But the book is, of course, not merely concerned with the first appearance of man on Earth. The whole subject of Old Stone Age man comes under review, and not only in Western Europe. Naturally, in the small compass of some 98 pages, the subject has to be treated in a summary fashion, but great skill in selection has been shown and anyone wanting to know something authoritative about palæolithic man would be well advised to start with *Man the Tool Maker*.

Canadian Arctic Geology

In 1955 the Geological Survey of Canada undertook a major project, appropriately named "Operation Franklin", to map the rocks of the Canadian Arctic Archipelago. Over an area of some 200,000 square miles, field parties were set down from the air at points selected from aerial photographs as the most suitable for detailed stratigraphical and structural studies, and were then serviced throughout the season by two heavy helicopters. A full account of this pioneer campaign has now become available (*Geology of the North-Central Part of the Arctic Archipelago, North-West Territories*. By Y. O. Fortier and others. Pp. 671+6 maps. Mem. 320, Geological Survey of Canada, Ottawa, 1963. Price 6.00 dollars). The principal geological formations discovered include the deposits of a miogeosyncline of Lower Palæozoic age, maybe more than 35,000 ft. thick, largely marine except for predominantly non-marine Upper Devonian; and those of a younger geosyncline (the Sverdrup Basin) comprising more than 40,000 ft. of marine and non-marine Pennsylvanian to Cretaceous strata with minor volcanic Cretaceous rocks and wholly non-marine Tertiary sediments. The longitudinal axis of this basin coincides with a zone of gypsum piercement domes and diapir folds. The survey has provided substantial indirect evidence that petroleum may occur in commercial quantity, although no live seepages were found. Coal is common in four formations—Upper Devonian, Upper Triassic or Lower Jurassic, Lower Cretaceous, and Upper Cretaceous or Tertiary, the last with seams measuring up to 30 ft. These important investigations have been continued annually since 1955 and in the current 1963 field season fifteen geologists of the Geological Survey of Canada, with nineteen ancillary staff, have been operating in the arctic District of Franklin.

Soils and Vegetation of the Congo

The considerable scientific work on tropical soils and crops carried out by the Belgians was largely responsible for the fifth International Congress of Soil Science being held in 1954 in the Congo. There have been numerous publications from this field, and this is one of a series on natural resources from L'Institut National pour l'Étude Agronomique du Congo (*Carte des Sols et de la Vegetation du Congo, du Rwanda et du Burundi*. 18: *Bassin de la Karuzi (Burundi)*. *A*: Sols. *B*: Vegetation. Notice Explicative de la Carte des Sols et de Vegetation. Par P. Pahaut et D. van der Ben. Pp. 48+5 planches. Brussels: Institut National pour l'Étude Agronomique du Congo, 1962). It consists of a memoir describing the general features of Rwanda and Burundi with a population of four million—75 per km²—entirely dependent on agriculture on the better soils of the hill slopes. This obviously presents a serious problem for the future of an undeveloped country. The Karuzi Basin was selected for detailed study. It is a region of 900 km² at an elevation of roughly 1,250–2,000 m lying some 130 km north-east of Lake Tanganyika. An outline of the geology and climate is followed by a discussion of the interactions of parent material, soil and vegetation. There is a description of the main physical and chemical properties of the soils and of their classification, and a chapter on the vegetation associated with the main soil groups. The vegetation types include aquatic, semi-aquatic or marsh associations, forest, the *Acacia abyssinica* valleys, the wooded and grass-shrub savannas and post-cultural natural growth. There are several photographs illustrating the nature of the ground and soil profiles and two maps of soils and vegetation on the 1 : 50,000 scale.

The British Institution of Radio Engineers: Awards

The following awards have been made by the British Institute of Radio Engineers for papers (given in brackets) published in the Institution's *Journal* during 1962: *The Clerk Maxwell Premium*, to M. W. Gough ("Propagation Influences in Microwave Link Operation"–July issue of the *Journal*); *The Associated Rediffusion Premium*, to I. J. P. James and W. A. Karwowski ("A Constant Luminance Colour Television System"–April); *The Vladimir K. Zworykin Premium*, to Dr. L. Kay ("Auditory Perception and its Relation to Ultrasonic Blind Guidance Aids"–October); *The A. F. Bulgin Premium*, to I. A. Harris ("Electron Transit Time and other Effects in a Valve Voltmeter Operating at Extremely Low Current"–November); *The Leslie McMichael Premium*, to W. L. Wright and S. A. W. Jolliffe ("Optimum System Engineering for Satellite Communication Links with Special Reference to the Choice of Modulation Method"–May); *The Charles Babbage Award*, to I. Aleksander and Dr. R. W. Scarr ("Tunnel Devices as Switching Elements"–March); *The Lord Rutherford Award*, to Dr. G. Dearnaley ("Semi-conductor Nuclear Radiation Detectors"–August); *The Marconi Award*, to A. Ciuciura ("Switchable 405/625 Line Time-Bases"–October); *The Arthur Gay Premium*, to D. Hinchcliffe, J. R. W. Smith and G. H. King ("Automatic Component Assembly in the Telephone Industry"–September); *The Dr. Norman Partridge Memorial Premium*, to G. D. Browne ("A Pulse Time Multiplex System for Stereophonic Broadcasting"–February); *The Sir Jagadis Chandra Bose Premium*, to Dr. B. R. Nag ("A Two-State Device with Two Inductively Coupled Colpitts Oscillators"–July).

The Institution of Electrical Engineers

Sir Albert Mumford, engineer-in-chief of the Post Office, has been elected president of the Institution of Electrical Engineers for the session 1963–64. The Council for next session will include: *Vice-Presidents*, B. Donkin, L. Drucquer, O. W. Humphreys, J. A. Ratcliffe, Dr. R. L. Smith-Rose; *Honorary Treasurer*, C. O. Boyse; *Members of Council*, S. S. Carlisle, Sir Robert Cockburn, A. R. Cooper, A. T. Crawford, D. Edmundson, G. Lyon, Dr. J. S. McPetrie, J. H. H. Merriman, Prof. C. W. Oatley, G. F. Peirson, M. J. L. Pulling, Dr. N. H. Searby, H. West, Dr. R. C. G. Williams. New chairmen of the three Divisions of the Institution have also been elected, as follows: Dr. R. C. G. Williams, chief engineer, Philips Electrical Ltd. (Electronics Division); Mr. C. D. Wilkinson, formerly chief engineer (reconstruction), National Coal Board (Power Division); Dr. J. R. Mortlock, assistant chief engineer, Associated Electrical Industries Power Group (Science and General Division).

The Corday-Morgan Memorial Fund Executive

The Corday-Morgan Memorial Fund Executive is to sponsor two tours to Africa during the winter 1963–64. Prof. R. A. Raphael, Regius professor of chemistry in the University of Glasgow, is to visit Commonwealth territories in East Africa, including Uganda, Tanganyika and Kenya, and Prof. G. Kenner, Heath Harrison professor of chemistry in the University of Liverpool, will tour Commonwealth countries in West Africa. The Corday-Morgan Memorial Fund Executive is derived from a bequest to the Chemical Society by Sir Gilbert Morgan, a past-president who died in February 1940. The Executive consists of the presidents and immediate past-presidents of the Chemical Society, the Royal Institute of Chemistry, and the Society of Chemical Industry, and its purpose is to promote the unification of the chemical profession within the Commonwealth. It seeks to achieve this object by the appointment from time to time of a lecturer to visit some designated area of the Commonwealth overseas. In general, the visitor will tour the main academic and, where appropriate, industrial centres to give informal colloquia as well as formal lectures, and to discuss problems of mutual interest in the countries visited. Further information can be obtained from the Secretary, Corday-Morgan Memorial Fund Executive, c/o The Chemical Society, Burlington House, London, W.1.

The Field Survey Association Annual Prize, 1963

The Field Survey Association is offering a prize of £50 for the best article in English on any subject that falls within the Association's scope and is published during 1963 in a professional or trade journal of any organization which carries out any of the activities included within those of the Association. The prize is open to any person under the age of forty on the date of submission of his article for publication. It is not necessary to be a member of the Association to enter for the prize. The rules of the prize, the history and objects of the Association and the conditions of membership can be obtained from the honorary secretary of the Award Committee, Commander R. Bill, Vickers House, Millbank Tower, London, S.W.1.

The Night Sky in October

Full moon occurs on Oct. 3d 04h 44m U.T. and new moon on Oct. 17d 12h 43m. The following conjunctions with the Moon occur: Oct. 3d 12h, Jupiter 4°N.; Oct. 20d 04h, Mars 4° S.; Oct. 26d 20h, Saturn 2° N.; Oct. 30d 17h, Jupiter 4° N. In addition to these conjunctions with the Moon, Venus is in conjunction with Spica on Oct. 6d 04h, Venus being 3° N. Mercury is a morning star, rising about 1h 40m before the Sun on October 8, and well placed for observation. Venus and Mars are too close to the Sun for observation. Jupiter is above the horizon most of the night, setting about two hours before sunrise on October 31. It is in Pisces, its stellar magnitude is −2·5 and its distance from the Earth on October 15 is 370 million miles. Opposition occurs on October 8. Saturn sets at 1h 15m, 0h 15m and 23h 15m at the beginning, middle and end of the month, respectively. It is in Capricornus, becoming stationary on October 21 and thereafter resuming its eastward motion among the stars. Its stellar magnitude is +0·8, and its distance from the Earth on October 15 is 875 million miles. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: Oct. 6d 23h 12·4m, δ Tau. (*D*); Oct. 7d 0h 14·2m, δ Tau. (*R*); Oct. 7d 0h 29·5m, 64 Tau. (*R*); Oct. 7d 0h 35·9m, 68 Tau. (*D*); Oct. 7d 1h 35·0m, 68 Tau. (*R*); Oct. 10d. 1h 44·4m, 63 Gem. (*R*); Oct. 13d 4h 22·4m, 37 Leo. (*R*); Oct. 29d 20h 28·5m, 30 Psc. (*D*); Oct. 29d 22h 34·9m, 33 Psc. (*D*). *D* and *R* refer to disappearance and reappearance, respectively. The Giacobinid meteors are active during October 9–10, but conditions for observation are rather unfavourable. The Orionid meteors are active during October 15–25, with a maximum on October 21; the radiant is near R.A. 6h 24m, Dec. +15°, and conditions for observation are very favourable.

University News:

Cork

Dr. M. J. T. Fitzgerald has been appointed reader in anatomy in University College, Cork (National University of Ireland). This is the first readership to be conferred since the foundation of the University.

London

The title of professor of computing science has been conferred on Dr. R. A. Buckingham, in respect of his post at the Computer Unit. The title of reader has been conferred on the following: Dr. W. C. Chaloner (botany), in respect of his post at University College; Mr. H. Billet (mechanical engineering), in respect of his post at University College; Dr. D. H. Martin (physics), in respect of his post at Queen Mary College; Dr. D. V. W. Parke (biochemistry), in respect of his post at St. Mary's Hospital Medical School.

Sussex

Dr. Z. Barbu, at present senior lecturer in the Department of Political and Social Theory at the University of Glasgow, has been appointed senior lecturer in social studies. Dr. R. R. Birss, at present lecturer in physics in the Department of Electrical Engineering, Imperial College of Science and Technology, London, has been appointed senior lecturer in experimental physics. Dr. S. Swierczkowski and Dr. G. L. Pratt have been appointed to lectureships in mathematics and chemistry, respectively.

Announcements

The eighteenth Calorimetry Conference will be held at the Petroleum Research Center, Bartlesville, Oklahoma, during October 16–18. Further information can be obtained from Mr. John P. McCullough, Bartlesville Petroleum Research Center, P.O. Box 1321, Bartlesville, Oklahoma.

The fourth international plastics industry fair will be held at Düsseldorf during October 12–20. The range of exhibits will cover main and ancillary materials, products, machinery and tools. Further information can be obtained from Nordwestdeutsche Ausstellungs- und Messe-Gesellschaft m.b.H.–NOWEA, 4 Düsseldorf 10, Postfach 10203.

An ordinary meeting of the Midlands Section of the Society for Analytical Chemistry will be held in Nottingham on October 15. A paper on "Sugars in Foodstuffs—some Newer Methods" will be presented and discussed at the meeting. Further information can be obtained from the Society for Analytical Chemistry, 14 Belgrave Square, London, S.W.1.

The laboratories of the Chalk Lime and Allied Industries Research Association will be open to visitors from industry during October 9–10. The Association is concerned with research and with providing technical information for the lime, sand-lime bricks and the ready-mixed mortar industries. Further information can be obtained from the Secretary, Chalk Lime and Allied Industries Research Association, Church Street, Welwyn, Herts.

A course in "Ultrasonic Testing", arranged by the South Wales Branch of the Non-Destructive Testing Society of Great Britain, will be held in Swansea on five consecutive Tuesday evenings, commencing October 1. The course will include: basic principles; methods and application; examination of castings; examination of forgings and plant in service; modern developments. Further information can be obtained from the Publicity Officer, the Non-Destructive Testing Society of Great Britain, 36 Willow Green, Ingatestone, Essex.

EDUCATIONAL POLICY IN BRITAIN

THE debate on educational policy in the House of Lords on July 24, which was opened by the Earl of Longford, brought a spirited defence of Government policy from Lord Newton, but added substantially little to the present debate. The Earl of Longford had pointed out that the cost of education had risen from £414 million in 1951–52 to nearly £1,250 million in 1963–64, and in the same period the percentage of the national income spent on education had increased from about 3·1 to 4·9. He agreed with Sir Edward Boyle's assumption that the reserve of potential ability among young people was not tapped to anything like the full extent. Lord Newton quoted also the view expressed by Sir Edward at Belfast on July 5 that if children were separated at any stage it should be done in their interests, and not because it pleased their parents or because of any social, class or colour distinction. We should work towards a situation in which every child had an equal chance of developing its interests and personality to the full. Defending the Government's impartiality regarding any particular pattern of secondary school organization, Lord Newton thought also that the achievements in school building had been considerable in terms alike of quantity and of economy and quality. This was due particularly to the work of the development group in the Ministry of Education, whose efforts now provided new schools at a cost, at constant prices, little more than half that in 1949. Lord Newton also referred to the need to re-examine many traditional assumptions and practices about the organization of schools in Britain. Sir Edward Boyle at Belfast had suggested that there might be room for more flexibility in the size of the groups to be taught, that we should ask what were the limits of an acceptable balance between men and women in the different stages of the schools system, what were the true functions of a highly trained teacher and whether their skills and experience were at present being dissipated in tasks which might well be delegated to other hands. All these questions, Lord Newton observed, required discussion, and, while in the recruitment of part-time teachers much of the initiative must rest with the schools and the local education authorities, the Government could help, particularly by commissioning research into the obstacles to be overcome and into the most fruitful lines of development. To reduce all classes to 30 or less would require a further 110,000 teachers, while the decision taken in January to increase the capacity of the training colleges to 80,000 students by 1970 would only give a net addition of 5,000 teachers during the decade.

In a maiden speech, Viscount Samuel, directing attention to the possibility of technological unemployment as the result of automation in industry, stressed the urgency of raising the minimum school-leaving age and referred also to its bearing on the wise use of leisure. Apart from Lord Taylor, speakers in the debate made little reference to the universities, but Lord James of Rusholme stressed the urgency of expansion and thought that the target of 170,000 students by the early 1970's was neither large enough nor likely to be reached without a new sense of urgency. He thought that the universities should see themselves as one end of a spectrum of higher education, distinguished from the others by the relative difficulty and originality of the ideas discussed and evaluated within their walls. He had few misgivings about standards, but some about the possible loss of liberty. While he himself regarded the Ministry of Education as a friend and an enlightened counsellor, it was vital that whatever administrative changes were made the essential liberties of institutions of higher learning should be defined by those who value them, and respected by those who administer them. The liberties to think, to speak, to publish the truth as one sees it; to decide what are the standards to be maintained and the studies to be pursued; to follow the argument where it leads—these are the essentials of teaching and research at the highest level, and on their preservation depends the quality of higher education.

In replying on the debate for the Government, the Earl of Dundee made no comment on Lord Tayler's suggestion that the Ministry of Education should take over from the Treasury its responsibilities for university education, but pointed out that by 1966–67 besides 150,000 students at universities there would be 137,000 students at teacher training colleges, colleges of advanced technology and other advanced technical colleges, or 10 per cent of the relevant age group, and a good deal higher in 1970.

RESEARCH INTO STRATEGIC TRANSPORT PLANNING

IN replying for the Government in a debate on the needs of transport for research in the House of Commons on July 30, which was opened by Mr. W. T. Rodgers, who asked specifically about economic studies, the encouragement given to postgraduate training, and research into strategic transport planning, the Parliamentary Secretary to the Ministry of Transport, Mr. T. G. D. Galbraith, said that the aim in the Ministry should be to keep a balance between action and research. Sometimes only when dealing with a problem in practice could one see where the difficulties lay, what additional information would be helpful, and where more research was needed. In transport, research was best concentrated, therefore, so as to help the solution of actual problems of policy and planning. This was recognized in the Hall Report, which gave the general outlook for traffic in 1981, and began with a statement of the fundamental problems confronting the Ministry before discussing possible lines of research. In transport in cities, for example, the difficulty was to obtain a solution which gave the right balance between conflicting interests. To do so it was necessary to discover the future pattern of personal travel, the strength of preferences for different patterns of travel, the future needs for the movement of goods, the pattern of transport facilities to-day, and the costs of adding to them in various ways, etc. Even with all the facts from such a survey, techniques of handling this knowledge were required and over the whole range of transport there were in fact two stages: research to discover the facts, and research to enable the right lessons to be drawn from them.

The Hall Report and the Beeching Report (see *Nature*, 198, 1233; 1963) were two examples of research which had been proceeding to obtain the facts; on the urban side, the Buchanan Report would soon be available, with its wide implications for city life, and the Ministry and the London County Council had jointly commissioned the London Traffic Survey, which would give detailed information of future traffic needs to enable these to be related to changes in employment, residential patterns, etc. The

survey was being undertaken jointly by British and American consultants working together. The Merseyside Survey should be ready this year and others would follow, while the City of Glasgow had requested a comprehensive survey to cover the Clyde Valley. Parallel with these special studies was a continuing programme of research to find out more about long-term trends in transport, examples of which were the large-scale sample survey of road–goods transport and continuing series of surveys of the ownership and use of private cars recently undertaken.

Mr. Galbraith pointed out that many of the skills required were those of economists, and for this interpretation it was necessary to rely largely on outside sources such as the universities, where transport research was developing in two ways: the first was in the growth of traffic engineering from engineering proper into the wider questions of the economics of transport, pricing, and so on. Secondly, there was increasing interest in transport as a subject of its own with the overall field of economics. The Government was endeavouring to increase the demand for traffic engineers by emphasizing to local authorities the value of such engineers, and the Ministry had been strengthening its links with the universities, and a useful two-way traffic in ideas was developing. It was proposed to use the token sum specially voted for research to stimulate more research and where appropriate to commission specific studies which would help in making policy decisions. An example was the cost–benefit study of investment in a railway electrification scheme just commissioned with British Railways, and the Road Research Laboratory had done a good deal of work on this technique in relation to roads.

ROTHAMSTED EXPERIMENTAL STATION

REPORT FOR 1962

THE size of a modern research station and the range of its activities is such that to keep in touch with its activities by reading the annual report is a major undertaking. Yet to have compressed a report on the work of Rothamsted into little more than 300 pages is in itself a substantial achievement*.

The place of Rothamsted in agricultural science is evident in the notes on personalities and events. Three members of the staff were elected to fellowships of the Royal Society, and invitations to staff members to visit other countries were more than could be accepted without detriment to their work.

The name of Rothamsted is particularly associated with work on soils, and on the conditions that determine their fertility. As Mr. F. C. Bawden, the director, remarks, "There are many reasons for needing to increase crop yields, but no minor one is that when agriculture is inefficient, it is profligate in its use of land". A great part of the work reported is directed towards the more economical use of this basic agricultural resource. The Soil Survey of England and Wales is based at Rothamsted, and Rothamsted provides a base for the Commonwealth Bureau of Soils. Through these two organizations its influence extends both over Britain and to the world at large.

The high level of fertility characteristic of the agricultural soils of England has been brought about very largely as a result of the work on manures and fertilizers at Rothamsted. Progress has been such that in recent years water has increasingly become the limiting factor in yields. Rainfall is barely adequate for unrestricted crop growth in eastern England, and even where the annual total is sufficient, irregularities in distribution give rise to shortages over periods long enough to depress yields. Under Penman's leadership, the Physics Department has opened up a most productive field of work on water supply in the soil and the consumptive use of water by crops. A few years ago it might have been argued that water, though the most important, was the least understood of the major plant nutrients. To-day, water ranks with the classic mineral elements in the fertility investigations at Rothamsted.

It was at Rothamsted that R. A. Fisher, whose sad death is recorded in this report, carried out the studies that established new standards of precision in biological experimentation. The enterprise that started with one man on a temporary basis is now a large and world-famous department, making extensive use of computers, and providing advice and guidance as well as computation service both in Britain and to Commonwealth countries overseas.

A report is primarily a record of work done, and this report is worth all its three hundred pages. In his wise and critical discussion of "The Use and Abuse of Toxic Chemicals" the director contributes to the assessment of the impact of research on agriculture and society. If it is permissible, after so comprehensive a report, to ask for a little more, one might hope that the director will in future use the general report more extensively for this kind of evaluation.

J. B. Hutchinson

RADIO RESEARCH 1962

THE report of the Radio Research Board*, under its new chairman, Dr. E. Eastwood, has recently been published. It states that 1962 was an eventful year in the life of the Radio Research Station in so far as its work is now making use of rockets and satellites for exploring the Earth's atmosphere out to more than 1,000 km, and obtaining a better understanding of the dependence of its physical characteristics on the Sun's radiation.

Two successful *Skylark* rocket firings have been made at Woomera, carrying experiments devised at the Station in collaboration with the University of Sheffield, and these are being continued during the present year. By co-operation with the Canadian and American authorities, the ionosphere is now being explored from above as well as from the older established ground observatories. In assisting other universities and organizations in the conduct of experiments in satellites which are relevant to the Station's research programme, the network of tracking stations under its control has accumulated extensive telemetry records on magnetic tapes. So far these records have been sent to the U.S. National Aeronautics and Space Administration for processing, but arrangements are now in hand for the first stage of the processing to be carried out at the Radio Research Station. Liaison with other workers in the United Kingdom is maintained through the British National Committee for Space Research under the auspices of the Royal Society.

In its programme of research on the ionosphere, considerable attention has been directed to exploring the

* Department of Scientific and Industrial Research Radio Research 1962: The Report of the Radio Research Board and the Report of the Director of Radio Research. Pp. iv+26+4 figs.+2 plates. (London: H.M.S.O., 1963.) 3s. net.

D-region (below 90 km), and the lower portion of the *E*-region up to about 100 km, since it is at these heights that the absorption of radio waves of all frequencies mainly occurs, and that the phase and polarization of the lower frequencies is determined. For this exploration of the lower atmosphere, a quasi-stationary pattern is set up by a vertical beam of waves at 200 kc/s, which are reflected back from the ionosphere. A rocket fired up through this pattern measures the characteristics—strength and polarization—of the field, and these depend on the height distribution of the electrons and on the frequency with which they collide with neutral molecules. The field pattern, as recorded on three mutually perpendicular aerials carried in the rocket, is complicated, and attempts are being made to explain the results on the basis of a 'model ionosphere' suggested by theoretical workers in the subject.

The staff of the Radio Research Station have taken full advantage of the opportunity provided by the Canadian 'Top-side Sounder' project to explore the characteristics of the ionosphere from above the height of maximum ionization. The satellite travelling at a height of about 1,000 km carries a complete ionosphere sounding station, and telemetry records have been obtained when the satellite passes over the Station at Slough and the out-stations at the Falkland Islands and Singapore. Some typical results are illustrated in the report, and these, together with others obtained by their Canadian and United States colleagues, have been discussed previously in *Nature* (197, 636; 1963).

For the past two years, oblique incidence sounding of the ionosphere has been carried out over a long-distance path between New Delhi and Slough. As the frequency is raised, the value at which the signal becomes weak or fades out is termed the maximum usable frequency. In this way, the highest useful frequency for a practical communication circuit over this path can be found at any time, and used to adjust the long-term average values which are provided from the prediction charts issued by the Station. Trials have been conducted over a number of paths in co-operation with the various civil and military authorities operating the related circuits. The technique should be found of advantage during the coming period of minimum sunspot activity when the usable frequencies will be severely compressed into a narrow part of the spectrum, and when any information which enables the operator to work outside it will be of great value.

To provide the facilities for the expansion of the research programme on the lines described here, some curtailment has been necessary on a few of the items which have received much attention in the past. The short-term ionospheric forecasting has been reduced to the provision of an ionospheric index for use with the long-term world charts which are now available for each of the 24 h. The information in these charts is based on the knowledge and experience obtained at the Radio Research Station in studying the characteristics of the ionosphere over more than two sunspot periods. The main programme of radio noise measurements, which was in progress for some ten years before the International Geophysical Year of 1957–58 and has continued since, has now been terminated. Finally, the preparation for publication of the *Abstracts and References* to radio literature, which has been the responsibility of the radio staff of the Department of Scientific and Industrial Research since 1926, was discontinued at the end of 1962, in the knowledge that the field surveyed was becoming increasingly covered by other abstracting services. Acknowledgment from users of the *Abstracts and References* is paid to the small section of the staff who, over the period of thirty-six years, devoted themselves to this work with unusual enthusiasm and energy.

Other features of the director's report show that he and his staff are maintaining and improving the high traditions of the Radio Research Station in advancing knowledge in the field of radio science in step with the contemporary progress being accomplished by the launching of satellites for space research. R. L. SMITH-ROSE

TELEMETRY APPLIED TO ENGINEERING AND MEDICINE

A MEETING was held at the Institution of Electrical Engineers on August 8 in connexion with the first International Telemetering Conference, which will be held at the Institution during September 23–27.

The chairman of the U.K. Organizing Committee, Dr. J. S. McPetrie, outlined the rapid growth of telemetry, the science/technology of measurement at a distance. He explained that the term telemetry applied to all cases in which the information from any form of measurement was transferred to some point other than that at which the measurement itself was made. This means that the measurement has to be made by a special type of equipment, known as a transducer, which transforms the result of the measurement into a form, usually electrical, suitable for transmission to the remote receiving point where the reading is required. Telemetry assumed great importance towards the end of the Second World War with the emergence of guided weapons and later satellites and space vehicles. In the development of such complex equipment, in which reliability of performance is of paramount importance, it is essential to know at all times how the various component parts are operating, and for this purpose some form of telemetry is essential. Telemetry, of course, is not limited to the fields of weapons and satellites but has many civil applications in which British scientists have played a leading part. All these fields will be covered by papers to be presented at the Conference.

The chairman then introduced Mr. Pruss, a member of the North American Organizing Committee. Mr. Pruss gave a brief account of the various conferences on telemetry which have been held annually in the United States since 1951. The committee responsible for these conferences, realizing that much work on the subject had been carried out in countries other than the United States, considered that the time had arrived when a conference of a more international character would be extremely useful. It was suggested, therefore, that such a conference should be held in Europe, preferably London. The Institution of Electrical Engineers and the British Institution of Radio Engineers agreed jointly to sponsor this conference. The international character of the forthcoming conference is indicated by the fact that the 500–600 delegates expected will come from some seventeen different countries, including the U.S.S.R., Poland, Australia, Japan and South Africa, while 59 papers will be presented by authors from the United States, the United Kingdom, Canada, Belgium, France, Australia and Japan.

Dr. R. H. Barker, who is chairman of the Programme Committee, next gave a brief summary of the scope of the papers to be presented at the Conference. It opens with an introductory session, at which three papers will be discussed. Two of these deal in a general way with the present state of the art of telemetry, while the third paper outlines the history of the extensive use of telemetry

in the United Kingdom by the electricity supply authorities.

In the second session, on "Industrial Systems", eight papers deal with such topics as the part telemetry has played in the control of a 2,300-mile pipeline for natural gas as well as in an investigation of the vibration of blades in a large turbine. The third session is on "Transducers" of different types, while the fourth session is devoted to "Geophysics and Biomedicine". This latter session should be of particular interest to the layman, as one of the papers describes experiments made using minute radio transmitters, so-called radio pills, in the human body for the diagnosis of disease. Prof. Stewart Mackay (United States), the author of this paper, was present at the meeting and gave an interesting summary of his research work.

The next three sessions, on "Recording", "Data Processing" and "Error Detection", are for the specialist, and with more than twenty papers on these subjects lively discussions are to be expected. The last session, the eighth, is on "Aerospace Systems". As this is a subject of the greatest topical interest, a whole day has been allowed for presentation and discussion.

One of the main functions of such a conference is to bring together for discussion and interchange of information in the laboratory workers in the particular field under review. For this reason, a number of visits of a technical nature have been arranged, and reference to them was made by Mr. J. Langham Thompson, who is chairman of the Visits Committee. Telemetry, he said, plays an important part in the remote control of electric power stations. Delegates will be able to see this on a visit to the main grid control centre of the Central Electricity Generating Board at Redbourn, near St. Albans. They will also be able to visit the Research Laboratories of the Central Electricity Generating Board, Leatherhead. For those interested in the medical aspects of telemetry, visits have been arranged to the National Institute of Medical Research at Mill Hill and the Medical Research Council Bioengineering Laboratories at Hampstead. Oceanographers will be able to see the work at the National Institute of Oceanography, Godalming, Surrey. Telemetry techniques are of great importance in coal mining and train signalling, so visits have also been arranged to the Mining Research Establishment, Isleworth, and the British Railways Track Control Centre, Hackney Downs. The various methods for tracking satellites and the procedures used for analysing the complex data from world-wide observations of orbiting satellites will be seen on a visit to the Radio Research Station, Datchet.

Immediately before the meeting, a cable was received from the United States offering to make available from the Pacific Missile Range in California a 'Constellation' aircraft fully instrumented as a flying laboratory and including telemetry equipment. Dr. McPetrie expressed the hope that the aircraft could be accommodated at the Royal Aircraft Establishment, Bedford, where a visit has already been arranged for those delegates interested in the flight testing of aircraft, one of the most important fields in the application of telemetry.

In answer to a question, Dr. McPetrie explained that the papers presented at each session would not be read by their individual authors but summarized as a group by a rapporteur who would be a specialist in the subject. With this procedure, it was hoped that more time would be available for discussion in which each author would have an opportunity to participate.

During the period of the Conference, an exhibition of telemetry equipment will be held at the Hilton Hotel. A shuttle coach service will be run between the Conference at the Institution of Electrical Engineers and the Hilton Hotel for the convenience of the delegates. A smaller exhibition illustrating particular points in the papers presented at the Conference will be arranged at the Institution.

J. S. McPetrie

THE MUSEUMS ASSOCIATION

THE sixty-ninth annual conference of the Museums Association was held at Newcastle upon Tyne during July 22–26 by invitation of the City and King's College and under the presidency of Sir Trenchard Cox, director of the Victoria and Albert Museum, London.

The conference opened with a welcome from the Lord Mayor and the Rector of King's College, followed by the presidential address. In this, Sir Trenchard naturally referred to the outstanding *Survey of Provincial Museums and Galleries**, recently issued by the Standing Commission on Museums and Galleries. He also stressed the importance of a definite policy for purchases and referred to the several building projects which are now engaging the activities of architects and directors.

The Rt. Hon. Sir Edward Boyle, Minister of Education, also addressed the delegates and especially referred to the importance of the various museum services for schools which now form such a prominent part of the museum movement in Britain. On many occasions he had witnessed the appreciation of the teaching profession for the services rendered. Referring to the *Survey*, he hoped that it would be implemented when Britain's economic position made this possible. He felt that teacher training colleges should include courses on the use that the profession could make of their local museums.

The main part of the conference naturally directed attention on the *Survey*, and delegates were favoured with the presence of the Earl of Rosse, chairman of the Standing Commission. The Hon. Nicholas Ridley and Mr. Kenneth Robinson also spoke and gave support for the main recommendations of the *Survey*, though the former was in favour of admission charges to museums. An informal vote emphatically rejected this suggestion. Mr. Robinson felt that poor museums discredited the movement and hoped that the Standing Commission would have made definite proposals on this subject.

In general, it can definitely be stated that the Conference was in general agreement with the recommendations of the Standing Commission, especially as regards the emphasis it placed on the future part to be played by the Area Museum Councils.

Members welcomed the information, given by the Countess of Albemarle, that the Carnegie Trustees hoped to continue their support for museums during the next quinquennium (1965–70).

At the annual general meeting, the conference agreed to new regulations regarding the award of the Diploma of the Museums Association whereby graduates will be exempted from the intermediate examination. The final examination will be taken by all candidates and include a thesis and a practical examination. It is hoped that revised regulations for the Technical Certificate will be ready for next year's conference, for which Dr. D. Dilwyn John, director of the National Museum of Wales, was elected president.

Social functions included receptions by the Lord Mayor and the Rector of King's College, visits to local museums and tours to the Roman Wall and Farne Islands.

WIND EFFECTS ON BUILDINGS AND STRUCTURES

SOME three hundred scientists and engineers representing twenty-one different countries gathered recently at the National Physical Laboratory, Teddington, for an International Conference on Wind Effects on Buildings and Structures which had been organized by the Laboratory in collaboration with the Building Research Station, the Institution of Civil Engineers and the Institution of Structural Engineers.

In view of the extent to which the safe and economic design of all forms of building and structure is dependent on a proper understanding of the effects of wind, it is perhaps surprising to learn that the Conference at Teddington represented the first major attempt in this field to bring together the research worker and the practising engineer. Most of the twenty-four papers presented at the conference were concerned with the wide range of research at present in progress at various establishments throughout the world and, naturally enough, much reference was made to the use of the wind tunnel as the chief research tool. However, it was encouraging to hear that with the development of new techniques and instrumentation it is proving less difficult than in the past to obtain measurements of wind loading on full-scale buildings.

The Conference was organized into six sessions each under the chairmanship of a distinguished engineer or scientist and each covering a different aspect of the problem. The first session, at which Sir Gordon Sutherland, director of the National Physical Laboratory, took the chair was restricted to the official opening and to an introductory paper by Mr. C. Scruton of the National Physical Laboratory. In his paper, Mr. Scruton reviewed the present position with regard to wind effects on buildings and structures. He directed attention to the fact that the terms of reference of the conference were restricted to the static and dynamic stability of structures and of structural members in wind and excluded such effects as the generation of noise, the promotion of fire and the penetration of rain. With the foregoing exceptions, the action of wind was classified into the static and dynamic effects; the former referring to the steady (time average) forces and pressures tending to give the structure or its component members a steady displacement and the latter to the tendency to set the structure oscillating. Mention was made of the Tay Bridge disaster of 1879 which prompted the engineers to make allowance for the wind in the design of the Forth Railway Bridge. He went on to consider the subjects of design wind speed, determination of the shape and pressure coefficients and the oscillatory effects of wind. Under each heading he stated the problems involved and demonstrated the part played by the individual contributions of the various authors to the understanding of the subject as a whole. In conclusion, a plea was made that the conference would stimulate a movement towards better liaison between the interested organizations in the various countries so that research could be co-ordinated and the results disseminated on a wider and more systematic basis than had been possible hitherto.

In session 2 the first two papers were both concerned with the structure of the wind. Mr. H. C. Shellard of the Meteorological Office (Britain) indicated some of the problems involved in making wind measurements and discussed the factors influencing the application of such measured data to the design of buildings and structures where the site conditions might be very different from those at the meteorological station where the measurements are actually made. Prof. A. G. Davenport (Canada) developed this theme further by introducing the concept of referring design wind speeds to the gradient height and relating the speed at lesser heights by factors depending on the terrain at the site of the structure. The statistical properties of turbulent wind were also discussed both in terms of the spectra and of the return period for the maximum wind speed. The probability theory used in his analysis of wind data yielded increased wind speeds as the life period for the structure is increased.

Papers by Mr. C. W. Newberry (Britain) and Dr. R. Pris (France) were both concerned with the measurement of wind pressures on full-scale buildings. The authors discussed the problems of instrumentation which had hitherto prevented comprehensive full-scale studies.

Session 3 was devoted to a discussion of the wind-tunnel techniques used for the investigation of wind effects on buildings and structures. The shape and pressure coefficient data in common use have been derived almost entirely from wind-tunnel experiments so that it is essential that such experiments should reproduce as closely as possible the behaviour of full-scale buildings and structures in the natural wind. A technique for reproducing the vertical gradient of the speed of the natural wind was described by Mr. N. Franck (Denmark). This was a practical interpretation of Jensen's model law and consisted of the application of coatings to the wind-tunnel floor ahead of the model with a variety of roughnesses designed to reproduce the gradient and turbulence properties of wind approaching over different types of terrain. Prof. W. D. Baines (Canada) reported on his work on the effects of wind gradient on tall skyscraper buildings and showed how, in the presence of a wind gradient, air currents can be induced to flow down the front faces of such buildings to give strong winds at street level. The wind-tunnel studies at present being undertaken in France and Belgium were presented in papers by Dr. R. Pris (France) and M. P. E. Colin and R. D'Have (Belgium) respectively. Both papers described work carried out in open-jet wind-tunnels using models mounted on ground plates. The last paper in this session, entitled "Model Simulation of Wind Effects on Structures" and presented by Mr. R. E. Whitbread (Britain), summarized the approach to wind-tunnel testing of models which has been adopted at the National Physical Laboratory. As well as discussing the effects of wind gradient, the paper introduced the concept of representing the dynamic properties of structures on models of reduced linear scale so that both the static and dynamic behaviour of a structure could be examined in the wind tunnel. The methods were illustrated by reference to an exhibition of models and techniques used at the National Physical Laboratory. The models included one of the General Post Office Tower for Central London and another of a 400-ft. office block. A further consideration introduced into the paper was that of the errors introduced into force and pressure measurements made on wind-tunnel models by an interference effect known as wake blockage. It was pointed out that this effect was of particular significance for tests on building models owing to the wide wakes generated by such models.

From meteorological observations and wind-tunnel investigations come most of the data used to formulate the wind loading clauses in the codes of engineering practice for building. With the previous discussions of both these aspects it was appropriate that papers on codes of practice should follow. These were provided by the papers of M. N. Esquillan (France) and Dr. M. Jensen and Mr. N. Franck (Denmark), who described the proposed revisions of the codes of practice for their respective countries.

The second half of this session introduced a different note into the proceedings which was to persist throughout the remaining papers, namely, the dynamic response of

structures to wind. The present codes of practice have been based on wind-tunnel test data obtained under steady wind conditions; whereas the data so obtained are applied to structures subject to the natural wind which can be both highly turbulent and continually varying in speed and direction. The assumption of a steady wind for design purposes implies that the fluctuations in speed and direction that do occur in the natural wind are so irregular and random that the structure does not respond to them any differently from its behaviour in a steady wind of the same average speed. This assumption was, however, challenged by Prof. A. G. Davenport (Canada). His paper on the buffeting of structures by gusts presented the results of an analysis of the response of a flexible structure to horizontal turbulence and showed, at least for structures of low natural frequency, that the deflexions produced can sometimes exceed the effect of the equivalent steady wind of the same average speed. In a second paper on the same subject, Mr. R. I. Harris, of the Electrical Research Association (Britain), described work with a similar approach which formed part of an extensive but not yet complete study of the special problems of gust effects on very tall transmission masts.

Both sessions on the final day of the Conference were devoted to problems of the oscillation of structures due to the action of steady winds. Since the collapse of the first Tacoma Narrows Bridge in 1940 designs for long-span suspension bridges have been subjected to extensive wind-tunnel testing prior to their erection. Even to-day, 23 years after the disaster, it is still desirable to carry out tests on models to ensure the stability of a particular design. Mr. D. E. J. Walshe (Britain) described the techniques which have been developed at the National Physical Laboratory for this type of testing. He discussed the use of spring-mounted models of typical sections of the suspended roadways and the requirements for such models to be representative of the complete bridge. Papers from the United States, Norway and France discussed the techniques used in these countries and demonstrated the international aspect of this particular problem.

Aerodynamic oscillation featured yet again in session 6, the final session of the Conference, when another problem of international interest, namely that of the galloping of electric power transmission lines, was the subject of four successive papers. The term 'galloping' has been used to describe the large amplitude oscillations which can be set up in transmission lines by wind. The cause can usually be attributed to certain de-stabilizing characteristics of the steady wind forces which often prevail when the transmission lines become coated with ice. In this session papers from Canada and the United States predominated. However, a paper presented by Mr. D. J. W. Richards of the Central Electricity Research Laboratories (Britain) described a case of galloping which occurred in non-icing conditions on the 5,310-ft. span of the 275-kV power crossing of the Rivers Severn and Wye. Wind-tunnel tests on sections of the conductor showed that the instability arose from peculiar aerodynamic effects associated with the lay of the outer layer of the conductor strands. Wrapping the conductor with polyvinyl chloride tape to produce a smooth profile was found to be an effective method of introducing stability to the crossing.

Slender structures with low natural frequencies such as stacks, towers and masts have a tendency to oscillate in response to the shedding of vortices at the natural frequency of the structure. That the vast majority of such structures do not oscillate can be attributed to the fact that they possess sufficient inherent structural damping to cancel out the aerodynamic excitation effect.

Modern methods of construction, although perhaps more economical and structurally efficient, tend to decrease the amount of structural damping and hence increase the liability to wind-excited oscillation. In his paper on this subject Mr. C. Scruton (Britain) mentioned these effects, and others, which influence the aerodynamic stability of stacks, towers and masts. The use of strakes with sharp-edged rectangular section wound as helices around the surface of cylindrical sections had proved to be a most effective device for the prevention of vortex-excited oscillations. A similar method was described in a paper by Professor Nakagawa (Japan). He had adopted a system of wire ropes as strakes, for application to tall stacks of welded steel construction in Japan. However, his advocation of the use of wire ropes appeared to be in disagreement with the statement made by Mr. Scruton in his paper that rounded strakes had been shown to be less effective than those of rectangular section.

R. E. Whitbread

INFORMATION *PER SE*

By Dr. PAUL S. HENSHAW

Division of Biology and Medicine, U.S. Atomic Energy Commission, Washington

RECEIPT and use of information is a feature in all living systems.

The information used by living systems is of three types: inherited, acquired and generated. Inherited information is that brought into organisms at the moment of conception; acquired is that brought in continuously during life by means of the sensory shield; and generated is that formed inside the system by interaction.

The means by which acquired information is received and developed varies widely among species.

Systems in organisms for processing acquired information have undergone evolutionary change comparable with that which has occurred in systems having to do with other functions.

Along with ability to detect and transduce stimuli, and along with ability to transmit information laden impulses, has come an increased ability to comprehend, to understand and to know, also an increased ability to imagine, feel, evaluate and make judgments. Acquisition of the more specialized information processing capabilities, and of the greater emotional capacities, have coincided with elaboration of the cerebral cortex.

In the human species, that is, the species considered to have the most advanced cerebral cortex, the ability to develop and utilize information greatly transcends that of other species. The human mind—the means by which we think—can be regarded as the most highly elaborated product of evolution.

Information is an entity apart from the means by which it is processed, the symbols by which it is represented, or the responses made to it. Messages contain intelligence (dispositional, organized, usable and available information), but as such do not themselves constitute intelligence.

Information can be transmitted and stored by means of impulses and symbols, but it exerts an influence only after removal from the encoded message and interaction with other information, as can happen in a cell, a brain or a computer.

Information can be regarded as existing in pieces or concepts, but probably not as units. Information, as such, is not amenable to quantitation in a manner comparable with that which applies to entities having force, mass or colour.

In last analysis, information consists of data, especially unrelated facts and statistics. With organization of data, intelligence is created and with further organization of organized data, intelligence is developed and enhanced.

Intelligence, like life, is a manifestation of sustained interaction. Each is associated with matter and fully dependent on it. Each, nevertheless, occupies a place apart from or beyond matter. Remove intelligence or life, or both, and the residue of constituent elements remains unchanged.

Life and intelligence are dispositional manifestations. Each consists of information processing carried along by energy systems utilized as vehicles. Life, as we tend to define it, is dependent on wet (protoplasmic) systems, whereas intelligence can exist and build in either wet or dry (hardware) systems.

Life and intelligence involve problem-solving processes with survival of organisms, or of ideas, as automatic and inherent goals. Both life and intelligence consist of self-organizing activities realizable only by means of the vehicles. Moreover, the thoughts evolved and the conclusions reached, if implemented, are implemented by means of the same vehicles in each instance. In final analysis, life and intelligence become reduced to interaction at the molecular level—interaction which provides opportunity not only for channellized energy utilization, but also for information storage and retrieval (memory), and for information and idea interaction (thought).

Early in the course of evolutionary development, as sustained energy processes acquired characteristics of life, there existed in the chemical sense a means and opportunity for receiving and utilizing information. With incorporation of particular molecular configurations in such systems, genetic information was acquired and particular classes of responses to the environment were ensured.

With development of DNA, a means was provided for replication and transmission of genetic information—and thereby opportunity for deterministic cycling of life, as done generally in plants.

With addition of neurones and neuronal networks, opportunity was provided for probabilistic information processing, that involving relevancy screening, judgments and decision-making, leading to purposive responses.

Elaboration of the body, of course, provided better vehicles—those which by means of sense organs and nervous systems enabled greater awareness of the environment, and which by means of musculature could make more meaningful responses to the environment.

More recently (in evolutionary time), with elaboration of the cerebral cortex, capabilities for feeling, abstraction, communication and organization have appeared.

It is noteworthy that in Nature, so far as is known, intelligence is associated only with living systems, and that ability to contemplate intelligence is associated mainly, if not altogether, with the human species. Since it is demonstrated that intelligence can generate when matter becomes organized in particular ways, there is little reason for expecting that intelligence is restricted to wet systems, such as known on Earth, or that the intelligence systems on the Earth may not change substantially or new ones form.

Both life and intelligence are modulated by information —inherited, acquired and generated. Beneficially adaptive use of information is an underlying aspect of each.

Intelligence is the substrate out of which ideas and concepts are formed. Ideas, like living things, are born; they undergo selection; and, in time, they may die.

In the physical world, change occurs in accord with natural forces; such change is compatible with reason and, therefore, said to be 'rational'.

In the sub-human living world, change is in accord with organic evolution—struggle for existence and survival of the fittest; this appears 'natural' and likewise rational.

In the world of human beings—that is, in relation to the species presumed to have the greatest capability for acquiring and utilizing information—change, as revealed by interaction, decision and behaviour, very often is not in accord with intelligence, reason or rationality. Honesty, pride, custom, dogma, principle, superstitition, deities, ethics, propriety, integrity, affection, virtue, honour and humour are features associated mainly with human beings; they involve rationality in the 'organic' and 'natural' sense only to a small degree.

In the world of human beings, perversity, morality and emotion are characteristics to be taken into account along with superior abilities in comprehension and understanding. These are attributes which, in particular, make the human species stand out as different from all others.

Perversity, as a characteristic of human life, is so strong that there is question as to whether the human species would long endure in a completely rational and Utopian world—one of perfection, such as is usually held up as the goal of human effort. There is thus the matter of the organizing power of informational elements beyond those regarded as strictly rational.

The fertilized ovum carries with it a legacy of genetic information—a 'blueprint' with a pattern for life to be read off in time. Continuously, the fertilized ovum or the growing organism, as the case may be, receives information from the environment which alters and helps determine the course of life.

Ideas, decisions and temperament, arising as they do from the interacting elements of stored and continuously received information, are largely the consequence of information previously accumulated, that is, of a conditioning derived from training and previous experiences.

There exists the group or mass mind as well as the individual mind. In the group, the same as in the individual, the kinds of opinions formed and the kinds of decisions reached are determined by the character of the available information, including disbeliefs as well as beliefs, including inaccurate, distorted and biased information as well as accurate and, indeed, including all the incorrect and correct elements of information programmed in to mould the ethical standards, to define the personality, and thus to form the id.

It is customary to speak of the 'soul' of a man, or the 'soul' of a people. Without implication of an entity beyond death of the body, such a term has usefulness here. In the same way that Japanese speak of the soul of a sword, meaning the metal as tempered for stamina and ability to cut through, so also can one speak of the soul of a man or of a people, meaning tempering, stamina and ability to cut through. The soul of a man or of a people can be regarded as the combined total personality, capability and emotionality.

The 'soul', it is submitted, is forged and tempered by the conditioning which results from the interaction of available information (genetic, acquired and generated) during the course of life. Additionally, it is submitted that the ability to feel—to experience emotionally—results from the information organizing aspects of the same interactions.

Since the inherited information that comes into the embryo has to do with capacity for learning more than with learning itself, it follows that what a man becomes to delineate him as man, and thereby the society, is determined largely by the soundness of information programmed in during life.

Rearing and training—the general educational conditioning primarily responsible for character determination —are matters over which man himself exercises the power of discretion.

Because of know-how already available enabling control of disease, development of resources, increase in productivity, management of populations, improvement of heredity, and designation of needed ethical standards, the human species could have for itself almost any standard

and level of living it would care to specify. Despite this favourable situation, however, it is evident that feelings of apprehension, fear and insecurity are intense and widespread.

In the period immediately ahead, it seems necessary to predict, man's greatest challenge will be that of how man will himself deal intellectually with his own intellectual achievements.

In our time—the period of the present generation—the emergence of nuclear and space developments have been seen and their impact felt. Now 'information science' is bursting on us, and while information science is not being heralded by events as spectacular as the detonation of bombs or the orbiting of satellites, its influence, it appears likely, will have an impact fully as great, and perhaps much more so.

'Cybernetics' is a term used in referring to the various fields and extensions of information science (or 'mind science') alluded to in the foregoing paragraphs. 'Heuristics' is another, and quite recently cyberculture[1] has been used. Cybernetics is defined as the 'science of control and communication in the animal and the machine'; heuristics involves the same considerations and extends to include problem-solving by means of search and discovery operative within the system itself; and cyberculture purports to apply the principles of cybernetics and heuristics in dealing with the operation of societies.

Despite the different points of emphasis, the theme of information science remains the same. It is how systems, living or non-living, regulate themselves, reproduce themselves, learn and evolve. It is how strategy and tactics are used in decision-making relative to rules and experience. Central is the question of how the various homoeostatic and reflexive mechanisms become goal-directed and self-adapting.

Governance is the point of departure under cybernetics, whereas under heuristics it is self-organization.

From the point of view of heuristics, there is emerging a mathematics and a practical circuitry which show how, with an adequate vehicle, information processing can be generative and beneficially adaptive with respect to specific goals—be they inherent (as in life processes), programmed in for a particular purpose (as in the case of computer analysis), or evolved (as occurs when complex problem-solving is done by the human mind). Heuristics portends a whole new science, and one with a bright and significant future.

With cybernetic and heuristic techniques, it is becoming possible to analyse the problem-solving strategies used by different human and animal brains and to see how these match with the training, personality and physical condition of individuals and species. By means of these techniques and the utilization of newer computer facilities, analysts are able to deal systematically with complex arrays of variables and thus to characterize the organizational and disorganizational forces operative in life processes and in social systems.

Because of prospective information storage and retrieval systems, combined with existent telecommunications facilities, there is early likelihood of bringing total accumulated knowledge (such as housed in the great libraries) to bear on a single problem or concept, also, for a single mind to probe all recorded subject-matter in selected fields, irrespective of location or language, and to consider the results of analyses quite beyond the capabilities of the human mind.

By means of evolving prosthetic devices intimately linked to human nervous systems, it is becoming possible for man to receive sensory stimuli directly from outside sources and to implement thoughts directly through machine devices, continuously and at great distances, also continuously in hostile or otherwise inaccessible environments (space, high-intensity radiation fields, extreme temperatures, microscopic dimensions, etc.).

Because of these various developments, there is the prospect that human minds and intelligence systems of various types can be combined in such a way as to interact as one great thought facility, doing so without the vagaries of language symbols. Indications are, therefore, of entry into realms of information utilization, concept formulation, analytical computation and emotional experience as yet not even imagined.

We are aware of how elaboration of the cerebral cortex provided a capability for intelligence that has set the human species apart, also that this was accomplished by means of organic evolution over a period of almost countless millennia. Now we are witnessing a transition fully as great, it would seem, but one taking place in an interval of time which, by comparison, is but a twinkling.

Leadership and an earned position of international public trust will accrue to the people most successful in meeting the challenge of information *per se*.

POSSIBLE ORIGIN OF THE LUNAR WALLED PLAIN PTOLEMAEUS

By R. G. STROM and Dr. A. PALM
Space Sciences Laboratory, University of California, Berkeley 4

PTOLEMAEUS, centrally located near the eastern border of Mare Nubium on the Moon, represents the northern member of a meridian alignment of craters or walled plains consisting of Walter, Regimontanus, Purbach, Arzachel and Alphonsus. It is about 159 km in diameter and about 2·4 km deep; the rim is hexagonal, and approximately level with the mean exterior surface. A light grey material on the floor covers numerous craters. These contrast sharply with younger, undamaged ones, many of which are superimposed on submerged features. Evidently, Ptolemaeus is a transition feature displaying characteristics of both the true craters and the circular maria.

The Ptolemaean floor features have been described by Alter[1] and Arthur[2], and regional tectonic analyses have been reported by Spurr[3] and von Bülow[4]. In the work recorded here the tectonic interrelations between the features in Ptolemaeus and the grid lineaments in the adjacent terræ have been investigated. The results favour the hypothesis advanced previously[1,3,5] that Ptolemaeus was formed by the collapse of a large segment of the crust during a degassing of the Moon's interior.

A generalized map of the regional grid systems and the pertinent Ptolemaean floor features (Fig. 1) was constructed from Plates 8, *C5-a*, *C6-a*, *-b*, *-c*, *-d*, *D5-a*, *-b*, *-c* in the *Photographic Lunar Atlas*[6] and from several photographs obtained through the courtesy of Dr. D. Alter. Fig. 2 shows a reproduction of plate *D5-a*. The nature of the lunar grid comprised of the Imbrium radial and the parallel systems has been examined by Spurr[3], von Bülow[4] and Fielder[7]. Arrays of ridges, valleys, rills, faults, and crater chains define the grids which extend along four or possibly five preferred directions. The valleys and ridges oriented S. 15° W. and S. 25° W. represent the Imbrium radial system, and the three lineaments oriented S. 55° W., S. 20° E., and S. 55° E. constitute the parallel system. The walls of Ptolemaeus and many of its interior features conform to these directions

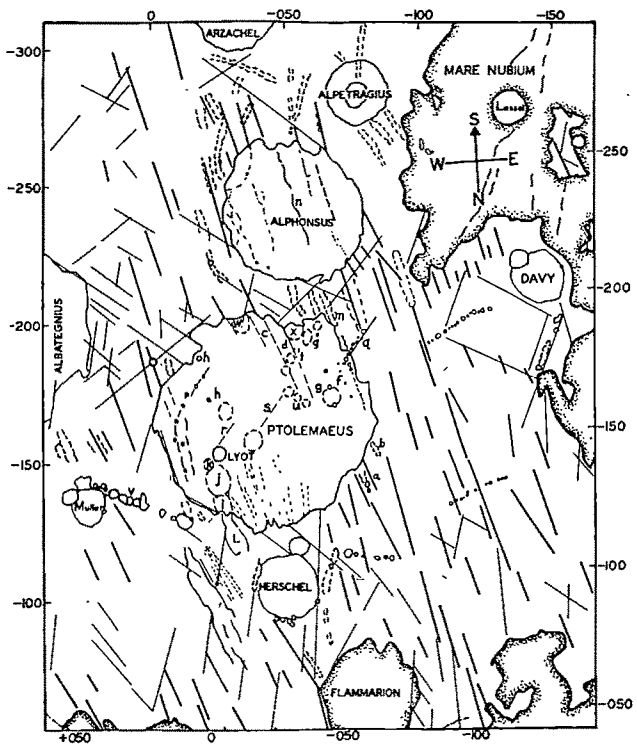

Fig. 1. Generalized tectonic map of Ptolemaeus and vicinity. Selenographic co-ordinates are those shown on Plate *D5–a*, in the *Orthographic Atlas of the Moon*

——, Imbrium radial lineament; ——, parallel grid lineament; ~ ~ ~, mare-type ridge; – – – – –, rill; ○, ghost crater; ○○○, probable coalescing craters

and, in some instances, are continuous with the grid lineaments of the adjacent terræ.

Imbrium Radial System. This system of valleys and ridges radiates from the border of Mare Imbrium for hundreds of kilometres and predominates in the vicinity of Ptolemaeus. The valleys have been identified as either grooves cut by ejecta from an Imbrium collision[8,9] or as grabens which resulted from tectonic processes during the formation of Mare Imbrium[3,4]. The valleys are oriented about two preferred directions which diverge by 15° and hence are not likely to have resulted from projectiles originating at Mare Imbrium. Some of the valleys represent distinct chains of coalescing craters such as those identified by *a* and *b* in Fig. 1. Frequently, the valley walls are scalloped at their intersection with the rims of the large craters. On the southern rims of Ptolemaeus and Alphonsus several scalloped valleys are arcuate at either their northern or southern ends. Although the linear portions of these valleys parallel the radial system, the arcuate segments deviate by 25°–40°. The departure from the radial direction, most pronounced at the northern terminus, suggests that the valleys may have been caused by internal activity along fracture zones.

On the southern floor of Ptolemaeus two shallow, apparently submerged valleys (Fig. 1, *c*, *d*) parallel the radial system and connect with re-entrants in the southern wall. Inside the valleys, which are approximately 50 km long and about 6 km wide, several ghost craters can be distinguished. On the north-western floor two parallel ridges (*e*) appear to outline a submerged valley or a chain of coalescing ghost craters. These shallow valleys may be the submerged equivalents of the adjacent terræ valleys.

A ghost chain (Fig. 1, *i*, *j*, *k*) on the northern floor parallels the radial system and merges with the prominent valley (*L*) which intersects the northern wall. In this area internal stresses may have caused the formation of a rift valley along which the ghost craters originated. The ghost crater (*i*) joining the terræ valley, and the two semicircular ghost rims (*w*, *x*) abutting against the southern wall, appear to have been bisected by faulting along the inner walls of Ptolemaeus. There, subsidence may have displaced the submerged craters to their present low position. The crater Lyot joins the row of ghosts about a point at which its western rim coincides with the eastern wall of the valley. Since the western rim of Lyot is some 180 m lower than the eastern rim[10], renewed activity along this fracture zone may have caused a slumping of the western rim.

A rill paralleling the eastern wall merges into a chain of at least three small craters and one of three large, coalescing craters along the base of the eastern wall. The latter chain aligns with a scalloped valley (Fig. 1, *m*) which intersects the southern wall. The entire group of features parallels the radial system and is-aligned with the central ridge (*n*) of Alphonsus. The interrelationship among the various dissimilar structures indicates that they may have coincided with a major zone of weakness associated with the radial system. Hence, the rill can be identified as a deep-seated fracture rather than as a superficial cooling crack. In addition, the three post-Ptolemaean crater alignments (*f*, *g*, *h*) and the eastern and western walls parallel the radial system.

A set of narrow valleys radiating from the young crater Herschel on to the floor of Ptolemaeus provides further evidence in support of a tectonic development of Ptolemaeus and of the regional Imbrium radial system. These valleys form a fan-like pattern the major axis of which parallels the Imbrium system. They resemble closely the sets of radial grooves near Aristillus and Aristoteles described recently by Fielder and Warner[11]. On the basis of semi-quantitative considerations, they have interpreted the grooves in terms of narrow rift valleys which resulted from the local enhancement of pre-existing, regional tensile stresses during the time of formation of the parent crater. Analogously, regional tensile stresses may have been present in the crust at the time Herschel originated. The regional stresses most likely assumed the same orientations since the central axis of the fan of valleys parallels the Imbrium radial system.

The morphology of the Imbrium radial system near Ptolemaeus and its relation to the diverse Ptolemaean floor features demonstrate that the valleys and ridges resulted from tectonic processes. Whereas the initial development of this system probably preceded the

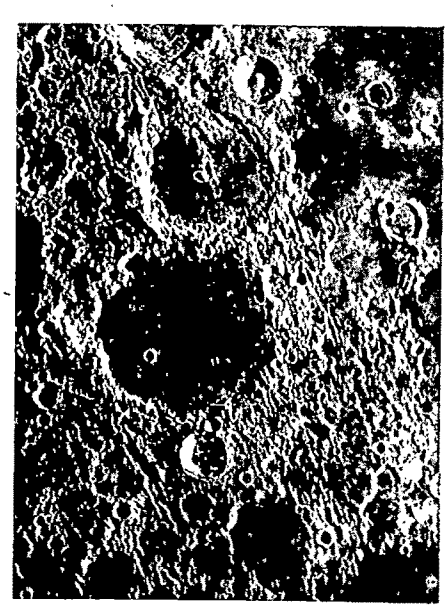

Fig. 2. Nubium N. Mount Wilson Photograph No. 124

inundation of Ptolemaeus, the alignment of the younger post-inundation features with the radial system suggests that the evolution may have continued beyond this stage.

Parallel grid systems. The Ptolemaean features are associated with the parallel grids in a manner analogous with the Imbrium radial system. The directions of the north-eastern, south-western, north-western, and part of the western walls coincide with those of the parallel grids as illustrated in Fig. 1.

On the floor of Ptolemaeus a crater alignment, a crater chain, several ridges, and a ghost chain coincide with the S. 55° E. oriented grid lineaments. The crater chain (Fig. 1, *q*) begins on the floor and continues through a gap in the eastern wall on to the terræ, where it parallels a prominent grid member. It should be noted that the eastern wall is offset at the common intersection of this crater chain with the lineament and the wall. These interrelations are indicative of faulting and possibly of horizontal displacement of the wall. A similarly oriented crater alignment (*p*) occurs on a prominent ridge on the western sector of the floor.

A group of ghost craters (Fig. 1, *t*, *u*) on the south-eastern quadrant of the floor appears to consist of two separate chains related to the north-west–south-east and north-east–south-west parallel grids. The southernmost chain (*t*) aligns with the lineament which forms the north-eastern wall of Alphonsus and with the prominent ridge (*r*), south-east of Lyot, and parallels the ridges (*p*, *s*) and the crater chains (*p*, *q*). The northern ghost chain (*u*) coincides with the north-east–south-west parallel grid in the adjacent terræ and with the north-eastern wall, which is flanked by a prominent crater chain (*v*). These ghosts probably represent submerged crater chains which originated along fracture zones. Alternatively, Dr. Alter has interpreted this group of ghosts as a single, arcuate chain outlining part of a large ghost crater. Both explanations are reconcilable provided the ghosts outline the rim of a large buried crater the north-western and south-western sides of which are bounded by fractures along which the ghost craters originated.

Conclusions. The tectonic relations between the diverse features in Ptolemaeus and the grid systems in its vicinity support the theory of an internal origin for the walled plain. The absence of external walls and the bisected ghost rims joining the inner walls which coincide with the tectonic grid systems, provide cogent evidence that Ptolemaeus collapsed along pre-existing zones of weakness in response to the withdrawal of support during a degassing of the Moon's interior. If Ptolemaeus had resulted from a meteoritic impact, the pre-existing craters would have had to originate after the collision. In a separate study it has been demonstrated, however, that the surface density of the combined ghost and post-lava craters closely resembles that of the craters in the adjacent terræ, and that the formation of many of the ghost craters probably preceded that of Ptolemaeus[12]. Consequently, a large segment of the crust may have been populated by numerous craters before subsidence set in.

Approximately half the number of craters more than 1·5 km in diameter is located on the rims of ghost craters, along the rill and on top of the ridges. This preferential location on structures constituting a mere fraction of the total area disproves a chance occurrence and signifies that many of the post-lava craters may have had an igneous origin.

As stated earlier, Ptolemaeus is one of several aligned, large craters or walled plains located along the western border of Mare Nubium. These aligned structures parallel the major axis of the mare, an admittedly subsided and lava-flooded area. During the subsidence of Mare Nubium, a major zone of weakness may have developed along its western margin together with degassing and collapse of the crust; the Straight Wall attests to renewed tectonic activity along this meridian zone.

The tectonic relationships between the Imbrium radial system and the Ptolemaean ghost features suggest that the formation of Ptolemaeus may have been contemporaneous with that of Mare Imbrium and that its evolution possibly proceeded in stages as follows: (1) subsidence of a segment of crust containing pre-existing structures; (2) formation of craters and related features within the subsided area; (3) inundation of the existing structures by lava and dust; and (4) formation of post-laval craters.

From the results of this investigation it is concluded that the lunar surface features with morphologies resembling those of Ptolemaeus may have had a similar origin.

We thank Dr. D. Alter for several photographs and for advice. This work was supported by a National Aeronautics and Space Administration grant, *NsG*-145-61, with funds administered by the University of California.

CHEMICAL ETCHING STUDIES AND TRANSMISSION ELECTRON MICROSCOPY OF SILICON CARBIDE

By T. GABOR and R. STICKLER

Westinghouse Research Laboratories, Churchill Borough, Pittsburgh 35, Pennsylvania

PREVIOUS investigations have shown that transmission electron microscopy is a powerful tool for the examination of structure and imperfections in metals and semiconductors[1]. For transmission electron microscopy, specimen thicknesses must be of the order of a few hundred Å. In the case of metals and semiconductors, especially germanium and silicon, the reactivity of the materials allows the use of relatively simple polishing techniques to prepare the thin films[2]. No method for the thinning of silicon carbide for transmission electron microscopy has been reported. Some initial investigations performed to develop a chemical polish for silicon carbide are now described. Specimens suitable for transmission electron microscopy were obtained by using molten lead oxide as a chemical polish followed by a final attack by a mixture of chlorine and oxygen. Lead oxide was not

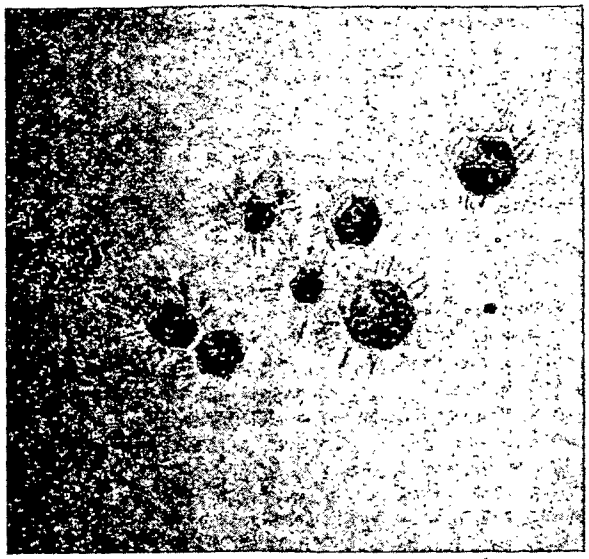

Fig. 1. 'Smooth side' after chemical etching with lead oxide. (Optical micrograph, × 200)

Fig. 3. 'Smooth side' after chemical etching with lead oxide plus lead fluoride. (Optical micrograph, × 500)

only suitable for the preparation of thin films but also had advantages over other etches for the preparation of smooth surfaces and for revealing dislocations.

Chemical polishing and etching. A suitable polishing agent for silicon carbide should have the following characteristics: (1) it should produce a smooth surface; (2) it should give reasonable etch rates at relatively low temperatures; (3) it should allow a controlled, reproducible reaction; (4) it should give volatile and/or soluble reaction products. No etchant was known[3] that would satisfy all these conditions. For example, the decomposition of sodium peroxide, one of the most commonly used etchants for silicon carbide, makes it impossible to obtain strictly reproducible conditions.

In searching for a reactant, lead oxide was found to satisfy all the requirements. The silicon carbide crystals were placed into small pits in a quartz block, and were covered with lead oxide. Etching was carried out at 800° C. Due to the relatively small amount of lead oxide that was used, a high concentration of lead silicates formed. These vitrified on cooling and were difficult to remove. The solubility of the glass could, however, be increased by adding about 5 per cent boric acid or borax to the lead oxide[4]. Hot concentrated potassium hydroxide solution was used to dissolve the reaction products, and this was followed by treatment with hot nitric acid. Alternatively, the bulk of the glass could be transformed into a white powder by boiling in hot concentrated nitric acid.

The rate of etching, calculated as the sum of etching taking place on both faces, was about 100 μ/h. The 'smooth side'[3] of a crystal after etching is shown in Fig. 1, while Fig. 2 shows the 'wormy side'[3] (this surface was obtained on a sample that was sandblasted before etching; see under).

Lead oxide forms a eutectic with lead fluoride[5]. This allowed etching at temperatures where, due to its relatively high melting point, lead oxide in itself could not be used. Thus, etching at 600° C for 1·5 h resulted in no detectable weight change (less than 1·0 per cent weight) although the dislocations were clearly revealed on the 'smooth side' (Fig. 3).

Sample preparation for electron transmission microscopy. Due to the brittleness of silicon carbide, only the centre portion of the specimen was thinned, while the remaining thick outer part served as support. The use of a jet-

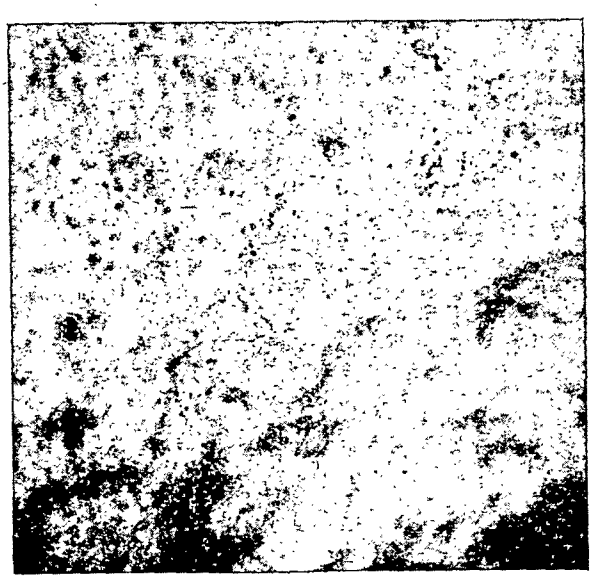

Fig. 2. 'Wormy side' after sandblasting and chemical polishing with lead oxide. (Optical micrograph, × 200)

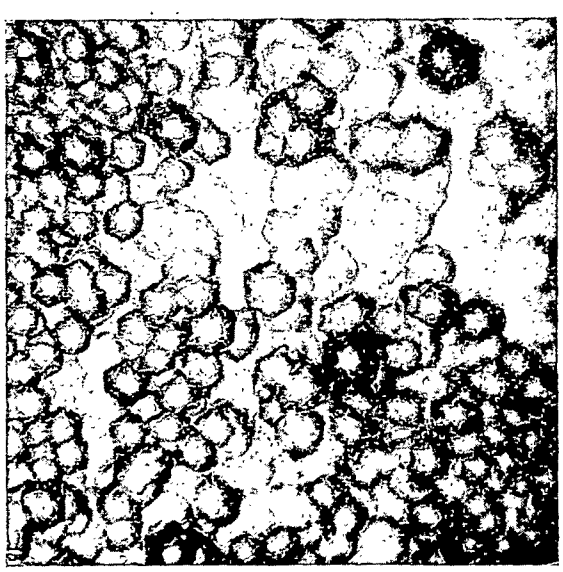

Fig. 4. 'Smooth side' after sandblasting and chemical polishing with lead oxide. (Optical micrograph, × 200)

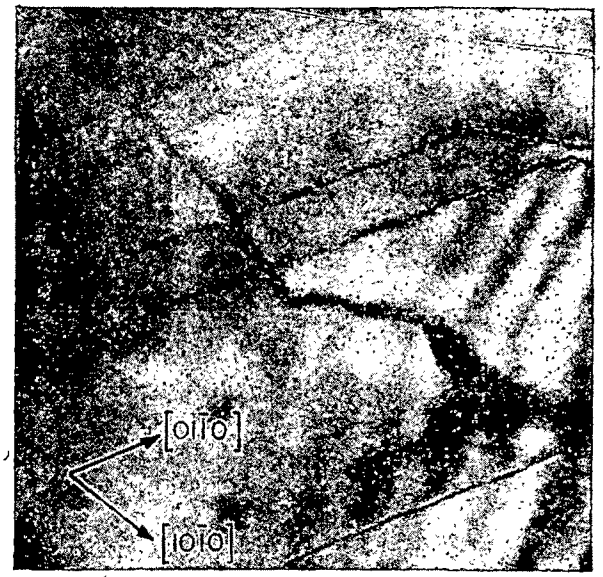

Fig. 5. Grown-in dislocations in silicon carbide film. (Transmission electron micrograph, × *c.* 22,500)

etching technique could not be considered, as no etchant for silicon carbide is known that would be liquid at moderate temperatures[3]. Therefore, an impression was sandblasted into the 'wormy side' of the silicon carbide crystal by using 320 mesh boron nitride powder. The impression was then filled with lead oxide and etching performed at 800° C. It was not possible to obtain a thickness at the bottom of the impression less than about 30μ, since thermal stresses between the lead glass and the silicon carbide film during cooling invariably caused fracturing of the thin silicon carbide portions. Therefore, the glass was removed and the polishing continued with a gaseous reactant.

It has been shown[6] that chlorine containing some oxygen attacks silicon carbide at 1,000° C, the etching rate being on the 'wormy side' approximately 20 times that of the 'smooth side'[6]. Chlorine (10 c.c./min) was passed over the crystals in a quartz tube (25 mm int. diam.) heated to 1,000° C, the outgoing end of the tube being reduced to 10 mm int. diam. along a length of 40 mm. The oxygen was provided by the back-diffusion of air through the open end of the tube. A white film, probably consisting of silicon dioxide, was formed on the silicon carbide crystals. This gave mechanical support to the thin portions of the specimens. After cooling to room temperature, the oxide film could be removed by aqueous hydrofluoric acid. Fig. 2 showed the surface of such a crystal. When sandblasting and etching was performed on the 'smooth side', a pitted surface was obtained (Fig. 4).

A transmission electron micrograph of a silicon carbide single crystal prepared by this method on the 'wormy side' is shown in Fig. 5. Dislocations can be seen as straight dark lines, with their longer portion approximately parallel to a < 0110 > direction in the plane of the film, while the shorter portions are inclined to the basal plane. The irregular broad dark line is due to incomplete removal of the oxide film. It should be noted that during the chlorine treatment no preferential etching attack occurred at places where the dislocations intersect the specimen surface.

ELECTROLYTICALLY INDUCED CONDUCTIVITY IN RUTILE

By Dr. P. F. CHESTER
Central Electricity Research Laboratories
AND
D. H. BRADHURST
Metallurgy Department, Imperial College of Science and Technology, London

HYDROGEN is known[1] to play an important part in the aqueous corrosion of certain metals. Recently, Leach *et al.*, investigating the aqueous oxidation of titanium and other metals[2–4], have found an apparent increase in the electrical conductivity of the oxide film after the evolution of hydrogen at the oxide surface. They suggest that atomic hydrogen enters the oxide and acts as an ionized donor impurity. This note reports experiments carried out on single-crystal rutile (TiO_2) which confirm the foregoing suggestion and yield more detailed information on the penetration of hydrogen into the oxide.

Single crystal specimens (8 mm × 2 mm × 1 mm) of pure rutile were brought to a suitable conductivity by vacuum reduction and the broad faces ground optically flat and parallel. One of the broad faces of each specimen was coated with gallium and the specimen was then mounted in quick-setting resin, with a copper wire making contact with the gallium-coated surface so as to leave only the opposite face of the specimen exposed. The rutile electrode so formed was immersed in 1 N sodium sulphate solution at room temperature, stirred by a stream of gaseous nitrogen, and a constant cathodic current of 1 m.amp/cm² was passed through it. The field in the sample at no stage exceeded 10 V/cm. The potential of the oxide surface was measured using a Luggin capillary calomel electrode, to ensure that the hydrogen evolution potential was always exceeded. After a given period of hydrogen evolution, the electrode was removed from the solution, the resin dissolved in acetone with the assistance of an ultrasonic agitator, and the gallium contact removed in aqua regia. The specimen was then washed in distilled water, dried, and remounted in quick-setting resin on a hardened steel polishing jig with the cathodically treated face exposed for subsequent conductivity measurements.

Current contacts were made with 'Aquadag' covering the end (2 mm × 1 mm) faces of the specimen and potential probes could be brought into contact with the exposed broad face. After each measurement of conductivity the sample was reduced in thickness by polishing the exposed face with Linde 'A' alumina. The smallest amount of material that could be removed in this way was 1 μ. A conductivity profile was derived from successive measurements of conductivity and thickness. As a check on the homogeneity of the starting material, a conductivity profile was determined with a vacuum-reduced sample which had not been exposed to hydrogen.

Conductivity profiles for several electrolytically treated samples are shown in Fig. 1, the times indicated on the curves representing the time of electrolysis. Anodic oxidation of electrolytically treated samples lowered the

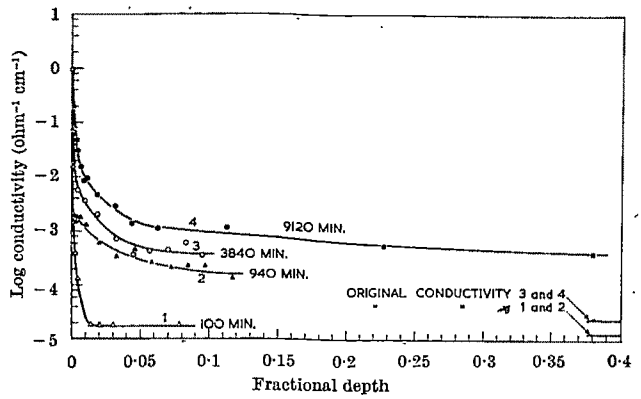

Fig. 1. Conductivity versus depth as a fraction of initial thickness for single crystals of rutile electrolytically treated for the periods indicated. Initial thickness (mm): (1) 1·029; (2) 0·964); (3) 1·081); (4) 0·989

conductivity considerably, but for durations of 1,000 min did not return the bulk conductivity to its original value.

There can be little doubt that the increase in conductivity produced by electrolysis is due to the presence and ionization of atomic hydrogen in the lattice—atomic hydrogen is already known to be a donor in ZnO with an activation energy of 0·04 eV (ref. 5). However, the form of the present results shows that the diffusion is not simple. In the first few microns the concentration falls off rapidly with an apparent diffusion coefficient in the range 10^{-11}–10^{-13} cm²/sec. At greater depths the fall-off is much slower and a considerable and relatively uniform concentration is observed at a depth of 100 μ or greater. In this region the apparent diffusion coefficient is in the range 10^{-7}–10^{-9} cm²/sec.

One interpretation of this behaviour, which may not be confined to rutile, involves a diffusion barrier at the surface resulting from chemical reduction of a thin layer of the oxide by the hydrogen. Surface reduction of this kind has indeed been reported by Thomas and Lander[6] for the case of ZnO in gaseous hydrogen. Such a layer is expected to be disordered, possibly with a high concentration of interstitials[7], and could well have a smaller diffusion coefficient than the bulk. Some evidence for the actual existence of a disordered surface layer was obtained by Prof. M. Blackman and Dr. N. D. Lisgarten of the Imperial College of Science and Technology using grazing incidence electron diffraction on a specimen that had been electrolytically treated for 960 min. The expected spot pattern was observed from the unexposed face while no pattern could be obtained from the treated face. A further point in favour of the surface barrier model is that the concentration deep in the crystal is observed to build up roughly linearly with time.

An alternative interpretation of the results is to regard the long range, fast, diffusion as being along dislocations and the short range diffusion as true bulk diffusion. The dislocation density in these crystals, as revealed by etchpits, is of the order 10^6/cm². Therefore only a small fraction of the evolved hydrogen atoms would be in a position to move directly into dislocations. The vast majority would have to undergo bulk or surface diffusion before reaching a dislocation and many would not reach one in the time-span of the experiment. If bulk and surface diffusion were much slower than diffusion along dislocations this model would account for the form of the present results.

Further experiments are planned to decide between the two interpretations. At this stage it is not possible to say which of the two observed ranges of diffusion coefficient applies to true bulk diffusion. However, it is clear that hydrogen is a very mobile and substantially ionized donor in rutile at room temperature.

It is a pleasure to acknowledge the co-operation of Dr. J. S. L. Leach, whose work on the role of hydrogen in oxidation stimulated this study. Thanks are also due to Mr. A. B. Willott for his experimental assistance. The work was carried out at the Central Electricity Research Laboratory and is published by permission of the Central Electricity Generating Board.

SOME REACTIONS OF OZONE IN DISCHARGE-FLOW EXPERIMENTS

By Dr. M. A. A. CLYNE, Dr. B. A. THRUSH and Dr. R. P. WAYNE
Department of Physical Chemistry, University of Cambridge

THE reaction mechanism of the recombination of oxygen atoms in the presence of molecular oxygen is generally assumed to be[1]:

$$O + O_2 + M = O_3 + M^{-} \quad (1)$$

$$O + O_3 = O_2 + O_2 \quad (2)$$

a small steady-state concentration of ozone being rapidly established. The following kinetic equations can be deduced:

$$-\frac{d[O_3]}{dt} = 2k_1[O][O_2][M] \quad (a)$$

and:

$$[O_3] = \frac{k_1}{k_2}[O_2][M] \quad (b)$$

These equations are not valid if significant amounts of ozone are removed by reactions other than (2). In this communication we report observations using discharge-flow systems which show that such reactions are important under these conditions, and in the chemistry of the upper atmosphere.

In recent experiments, we have studied the reaction between ozone and oxygen atoms, in the absence and presence of molecular oxygen by chemiluminescence methods.

Oxygen atoms free from molecular oxygen were obtained by titrating N atoms with the stoichiometric quantity of carefully dried nitric oxide[2–4]:

$$N + NO = N_2 + O \quad (3)$$

The nitrogen atoms were produced in an 18-Mc/s electrodeless discharge through British Oxygen Company 'white spot' nitrogen which had been purified by passage over heated copper turnings at atmospheric pressure, then through a narrow trap packed with glass wool, maintained at −78° C and, finally, at low pressure, through another packed trap at − 196° C. A discharge through 1 per cent oxygen in an argon carrier was used to produce oxygen

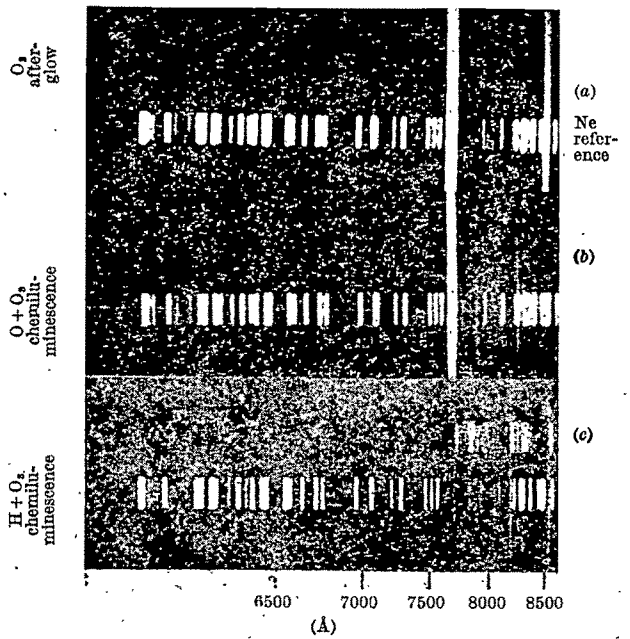

Fig. 1. Spectra of the chemiluminescent reactions of oxygen and hydrogen atoms with ozone

atoms in the presence of relatively small amounts of molecular oxygen.

When dry ozone is added to the oxygen atoms produced by either of these methods, a faint infra-red chemiluminescence is observed. For short reaction times, the intensity of this emission is proportional to the concentration of ozone added. At longer reaction times, the ozone concentration decays quite rapidly downstream, according to a first-order rate law. In these experiments, $[O] \gg [O_3]$, and the rate of ozone removal increased with oxygen atom concentration. Assuming that reaction (2) accounted for all the ozone removal, values of k_2 between 4 and 6×10^{10} cm^3 mole^{-1}s^{-1} were derived at room temperature. These may be compared with values of 2×10^{10} cm^3 mole^{-1}s^{-1} obtained by Leighton *et al.*[5], and $1{\cdot}5 \times 10^{10}$ cm^3 mole^{-1}s^{-1} by Phillips and Schiff[6] also in flow systems. These are all considerably higher than the value of $k_2 = 2{\cdot}3 \times 10^9$ cm^3 mole^{-1}s^{-1} obtained from Benson and Axworthy's[7] data on the thermal decomposition of ozone corrected for the revised dissociation energy of oxygen[8,9].

The infra-red chemiluminescence was photographed on Kodak I–*N* plates, using a Hilger *f*/4 spectrograph. This spectrum is reproduced in Fig. 1 and, apart from the oxygen atmospheric band ($^1\Sigma_g^+ \rightarrow {}^3\Sigma_g^-$), which appears as a background in experiments where oxygen is passed through the discharge, it shows the Meinel bands[10] of OH (vibration–rotation spectrum of OH from levels up to $v = 9$), which have been shown by McKinley, Garvin and Boudart[11] to be produced in the reaction:

$$H + O_3 = O_2 + OH \qquad (4)$$

A spectrum obtained from the H + O_3 reaction is also shown to illustrate that the bands observed are identical. The observation of the Meinel bands in the experiments with O atoms is somewhat surprising, since the purification methods used imply that the H atom concentration must be much less than the O atom concentration. Reaction (4) is extremely rapid at 300° K. McKinley and Garvin[12] have shown that $k_4 > 2 \times 10^{12}$ cm^3 mole^{-1}s^{-1} and Phillips and Schiff[13] report a value of $k_4 = 1{\cdot}6 \times 10^{13}$ mole^{-1}s^{-1}. In the presence of oxygen atoms, OH radicals produced in reaction (4) will rapidly regenerate H atoms by the reaction:

$$O + OH = H + O_2 \qquad (5)$$

which also has a very high rate constant[14,15]. Reactions (4) and (5) together provide an H atom catalysed removal of ozone, which has the same overall stoichiometry as reaction (2) between O and O_3. Putting $k_4 = 1{\cdot}6 \times 10^{13}$ cm^3 mole^{-1}s^{-1}, the hydrogen atom concentration needed to account for all the ozone removal observed in our experiments is 7×10^{-13} mole cm^{-3}. This corresponds to about 20 parts per million of H atoms in the flow system, or a ratio of O : H of 300 : 1. It is clear that data regarding the rate of removal of ozone and its steady-state concentration in discharge flow experiments must be regarded with great caution until satisfactory methods have been developed for eliminating traces of hydrogen-containing substances from the gases used. We therefore consider that the corrected value[8,9] of Benson and Axworthy's rate constant[7], $k_2 = 3 \times 10^{13} \exp(-5600/RT)$ cm^3 mole^{-1}s^{-1}, is the most reliable at present available as no H atoms would be present in this system; and their expression is consistent with data on the thermal decomposition of ozone in flow systems[16] and in shock tubes[9]. The high intensity of the Meinel bands in night sky spectra is clearly due to the high ratio of $k_4 : k_2$.

Although the reactions of nitrogen dioxide are very similar to those of ozone, yet traces of hydrogen atoms probably do not affect the reaction kinetics in the same way. The process:

$$H + NO_2 = NO + OH \qquad (6)$$

is very rapid[13,17] ($k_6 = 2{\cdot}9 \times 10^{13}$ cm^3 mole^{-1}s^{-1}) (ref. 13), but the reaction of oxygen atoms with nitrogen dioxide:

$$O + NO_2 = NO + O_2 \qquad (7)$$

is very much faster than with ozone[18] ($k_7 = 2 \times 10^{12}$ cm^3 mole^{-1}s^{-1}), and traces of hydrogen will make little difference to the rate of nitrogen dioxide removal.

At higher pressures and higher initial oxygen atom concentrations, emission of the oxygen atmospheric band[19] becomes more intense, and the behaviour of oxygen molecules in the $^1\Sigma_g^+$ state can conveniently be studied downstream from a silver foil, which greatly reduces the concentration of oxygen atoms in the flow line.

In these experiments, the partial pressure of $O_2(^1\Sigma_g^+)$ was found to be $10^{-4} - 10^{-3}$ mm mercury. This was determined from measurements of the absolute emission intensity of the oxygen atmospheric bands, for which the radiative transition probability is known to be 0·14s^{-1} (refs. 20 and 21). Introduction of NO, NO_2 or O_2 to the flow line had no significant effect on the intensity of the atmospheric band emission, but the addition of ozone greatly reduced the strength of these bands, and intensified the air afterglow emission (which is associated with the reaction:

$$O(^3P) + NO + M = NO_2 + M \qquad (8)$$

showing that $O(^3P)$ atoms are formed. We therefore conclude that the reaction:

$$O_2(^1\Sigma_g^+) + O_3(^1A) = 2O_2(^3\Sigma_g^-) + O(^3P) \qquad (9)$$

which is 13 kcal/mole exothermic, occurs to an appreciable extent, although some dissociation of ozone may be produced by other metastable species.

A reaction of this type will regenerate oxygen atoms removed by reaction (1), thereby reducing the apparent value of k_1 if equation (*a*) is used to analyse the experimental data. Such processes may be important in the work of Kaufman and Kelso[19,22], who observed that the apparent value of k_1 in the products of a discharge through oxygen decreased when the power of the discharge through oxygen decreased when the power of the discharge was increased, or when a higher proportion of the oxygen used was passed through the discharge. Both these procedures would be expected to increase the number

of metastable oxygen molecules in the reaction system which could decompose the ozone as it was formed.

To summarize, the presence of metastable excited oxygen in the flow experiments can affect both the kinetic equations (*a*) and (*b*), and may account for the wide range of published values for k_1 (ref. 22). The presence of traces of hydrogen atoms in the discharge products will affect equation (*b*), but not (*a*). It is interesting to note that the presence of hydrogen atoms would minimize the effect of excited molecules by catalysing the ozone removal with the same stoichiometry as reaction (2).

We thank Prof. R. G. W. Norrish for many helpful discussions. We also thank the Department of Scientific and Industrial Research for a special research grant, and for a research studentship to one of us (R. P. W.).

SEPARATE SYNTHESIS OF FIBRILLAR AND MATRIX PROTEINS IN THE FORMATION OF KERATIN

By A. M. DOWNES and L. F. SHARRY

C.S.I.R.O., Division of Animal Physiology, Ian Clunies Ross Animal Research Laboratory, Prospect, New South Wales

Dr. G. E. ROGERS*

C.S.I.R.O., Division of Protein Chemistry, Parkville, N.2, Victoria

THE mechanism by which sulphur is incorporated into the growing hair is not clear. Harkness and Bern[1] interpreted the intense localization of [^{35}S]cyst(e)ine in the keratogenous zone as showing that there is an absolute increase in sulphur in the hair above that in the cells of the bulb, in support of the theory of sulphur-enrichment[2,3] during keratinization. They pictured the formation of keratin as a *de novo* synthesis in the keratogenous zone, with the proteins carried up by cells from the matrix (bulb) serving as partial precursors (amino-acid sources) but with the cyst(e)ine being largely taken up from the blood by the keratogenous zone. However, the autoradiographic evidence does not rule out the possibility that, prior to or simultaneously with keratinization, there is hydrolytic removal of amino-acids which do not contain sulphur, resulting in an apparent enrichment with sulphur[4].

Rothman[5] supported the idea that in keratinizing structures cellular proteins are hydrolysed to free amino-acids which are then converted to keratin in the keratogenous zone. In support of this, De Bersaques and Rothman[6] found that several labelled amino-acids, including cysteine, were simultaneously incorporated into growing hairs in guinea pigs. They concluded that keratins are formed directly from free amino-acids, and that there is no superimposed cystine incorporation into pre-formed proteins.

A possible mechanism suggested by Rudall[3] and favoured by Mercer[7] from electron microscopic evidence is that relatively sulphur-poor microfibrils are synthesized in the lower regions of the follicle and as the cells containing them move through the keratogenous zone an entirely different protein, sulphur-rich and non-fibrous, is synthesized there *de novo*. This protein(s) forms a cementing matrix in which the fibrils become embedded and covalently linked by disulphide bonds. Alternatively, the matrix protein may be synthesized directly on the filaments, establishing an actual peptide linkage with existing polypeptides[7]. Rogers[8] mentioned other possible mechanisms in which only matrix protein might be enriched with sulphur by a reaction of the serine side chains with homocysteine derived from free methionine.

The proteins of fully hardened keratins can be made soluble by either oxidation[9–11] (giving keratoses) or reduction[12] (giving kerateines). After either treatment the proteins can be fractionated into two main groups. One group is poor in sulphur and of high molecular weight: α-keratose and kerateine *A*. The other is rich in sulphur and of low molecular weight: γ-keratose and kerateine B. These two distinct protein types, generally termed the low-sulphur proteins and the high-sulphur proteins, are at present held to be derived respectively from the fibrillar (microfibril) and matrix components of the original keratin[8,13]. The 'prekeratins' of cow's horn[3] and of the wool root[14], which occur completely in the sulphydryl form, can also be isolated and separated into two similar fractions. The rationale behind this relationship is based on extensive but mainly indirect evidence except for an electron microscopic study which indicated that γ-keratose preferentially extracted from oxidized wool originates in the matrix[15].

We have re-investigated the problem of sulphur incorporation during keratinization in the wool follicle based on the assumption of the two-stage synthesis[7]. Thus if enrichment with cystine is a process essentially involving the matrix protein, it follows that, after injecting [^{35}S] cystine into a sheep, the specific activity of the sulphur should be higher in the γ-fraction than in the α-fraction. For such differential labelling to be readily detectable there has to be a reasonable time-lapse in the process of keratinization between initial synthesis of the fibrillar (low-sulphur) protein and the synthesis of the matrix (high-sulphur) protein.

Experimental procedure for [^{35}S]*cystine labelling of follicle tissue.* Each of four sheep *S*1, *S*2, *S*3, *S*4 was given an intravenous dose of DL-[^{35}S]cystine hydrochloride

* Present address: Department of Biochemistry, University of Adelaide, Adelaide, South Australia.

Table 1. Specific Activity (c/m at Infinite Thickness) and Sulphur Content* of 'Prekeratin' Proteins

Fraction	*S1* c/m	*S1* % S	*S1* c/m/%S	*S2* c/m	*S2* % S	*S2* c/m/%S	*S3* c/m	*S3* % S	*S3* c/m/%S	*S4* c/m	*S4* % S	*S4* c/m/%S
Whole protein	469, 466 → 467	1·74	268	92, 89 → 91	1·62	56·1	376, 356 → 366	1·96	187	355, 355 → 355	1·81	196
High-sulphur protein	1,117, 1,103 → 1,110	3·53	314	216, 222 → 219	3·17	69·1	863, 883 → 873	3·61	242	752, 760 → 756	3·23	234
Low-sulphur protein	359, 343 → 351	1·48	237	68, 74 → 71	1·42	50·0	232, 228 → 230	1·41	163	242, 248 → 245	1·46	168
Specific activity ratio: low-sulphur/high-sulphur			0·753			0·723			0·674			0·718

* Sulphur analyses by Dr. K. W. Zimmerman, C.S.I.R.O., Microanalytical Service, Melbourne.

(about 100 μc.; 1 mg) diluted with 5 ml. of 0·9 per cent sodium chloride. After intervals of 1·0, 1·1, 4 and 17 h respectively, the sheep were killed and flayed and the wool roots removed from the skin by the wax sheet method[14].

The degree of labelling of sulphur was examined in the low- and high-sulphur proteins from two regions of the wool root, namely, the prekeratin protein developing in the keratogenous zone and isolated by dispersion with urea[14], and secondly, that portion of each wool root not dispersable by urea (wool root residue) which contained the keratin produced in the time interval after the radioactive dose had been given (Fig. 1). The maximum time allowed to elapse after administration of a dose was only 17 h and was insufficient for the labelled zone in the keratinized fibre to reach the skin surface. The wool root residue contained this zone and a quantity of unlabelled fibre grown earlier.

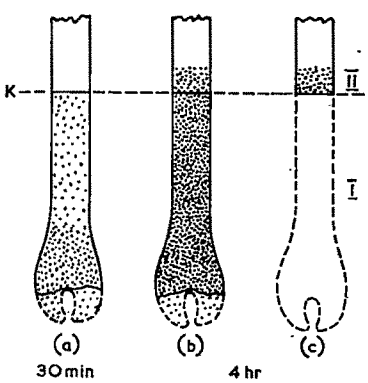

Fig. 1. Diagram of the keratin-forming region (lower third) of wool or hair follicles. The part shown approximates that isolated by the wax sheet method and includes much of the region where the labelling with sulphur-35 takes place. Above level *K* keratinization is complete (*a*) Shows the relative distribution of label (stippling) found 30 min after injection; (*b*) is distribution of label 4 h after injection, and shows that some label is now present in the keratin; (*c*) illustrates situation (*b*) after removal of the prekeratin by urea from the keratogenous zone, I, leaving behind the residue of keratin, II

'*Prekeratin*'. After isolation of the wool roots, a sample was set aside and the remainder was immediately extracted with 8 M urea containing iodoacetic acid at *p*H 8, and the extract fractionated[14] into high- and low-sulphur protein fractions. The extracted roots were washed well with water, ethanol, and ether, and dried.

The soluble fractions prepared from the urea extract and finally freeze-dried were analysed for sulphur, and their specific activities determined by direct counting of infinitely thick samples (1 cm²) with an end-window Geiger–Müller counter. Before they were assayed, the proteins were allowed to stand overnight exposed to the laboratory air to prevent changes occurring in the counting rates due to the uptake of moisture. Since the amount of dry matter was afterwards found to be practically the same for each sample (89·3 ± 1·2 per cent), the counting rates may be presumed to give reliable relative values for the specific activities. The results are shown in Table 1 together with the ratios of the counting rates to the sulphur contents; these ratios are proportional to the specific activities of the sulphur in the respective fractions. In each case the value for the low-sulphur protein was about 30 per cent lower than for the high-sulphur protein.

Samples (100–200 mg) of the high-sulphur and low-sulphur proteins from three of the experiments (*S2*, *S3*, *S4*) were oxidized as described by Myers[16] for wool. Benzidine sulphate was prepared from each and assayed as described here. The relative specific activities obtained by this direct method (0·700 (*S2*); 0·649 (*S3*); 0·831 (*S4*)) agreed reasonably well with those previously calculated (Table 1).

To show that these differences in specific activity were not simply due to the fractions containing different proportions of some non-radioactive sulphur compound, samples of the high-sulphur and low-sulphur fractions from *S3* were hydrolysed and the hydrolysates eluted from an ion-exchange column as described by Gillespie and Springell[17]. In each case the only detectable radioactivity in the effluent was associated with S-carboxymethyl cysteine (SCMC), which accounted for 90 per cent of the radioactivity put on the column. The relative specific activities of the two lots of SCMC were calculated from the counting rates of 0·1 ml. aliquots taken from the appropriate fractions of the effluent and counted on paper by a liquid scintillation method[18] and from the optical densities at 570 mμ obtained by treating other 0·1-ml. aliquots of the same fractions with ninhydrin[19]. The results showed that the specific activity of the SCMC from the low-sulphur protein was 74 per cent of that from the high-sulphur protein.

Labelling in the keratin. 1 g of the wool root residues from each of the experiments *S3* and *S4* was oxidized with performic acid[11] and fractionated into α- and γ-keratose. The sulphur contents were measured by the oxygen flask method, essentially as described by Fritz and Yamamura[20] and Lysyj and Zarembo[21]. The specific activity of each fraction was measured by combustion and liquid scintillation counting, substantially as described by Kalberer and Rutschmann[22]. From the results which are shown in Table 2, it can be calculated that the specific activity of the sulphur in the γ-keratose from *S3* (4 h after injection) was about 11 times that of the sulphur in the α-keratose. The corresponding ratio for *S4* (17 h after injection) was 4·4. The radioactivity in the wool root residues in these experiments includes the fully hardened keratin formed soon after the injection (Fig. 1).

Table 2. Specific Activity and Sulphur Content* of Keratoses Isolated from Wool Root Residues (Keratin)

Sample	*S3* c/m/mg	*S3* % S	*S4* c/m/mg	*S4* % S
Wool root residues	7·27, 5·25 → 6·3	2·65, 2·93 → 2·79	21·9, 23·8 → 22·9	2·51, 2·61 → 2·56
Oxidized wool root residues	5·15, 5·64 → 5·40	—	18·9, 18·2 → 18·5	—
α-Keratose	0·509, 0·543 → 0·53	1·71	4·09, 4·45 → 4·27	1·79, 1·77 → 1·78
γ-Keratose	13·18, 13·11 → 13·1	3·79	43·0, 40·1 → 41·5	4·00, 3·80 → 3·90

* See footnote to Table 1.

General conclusions. In previous work, the specific activity of the sulphur in the α- and γ-fractions from the first labelled wool obtained in successive clippings from sheep dosed with cystine labelled with sulphur-35 has been measured (Downes and Sharry, unpublished work), and although small differences were detected the results were inconclusive. In the present study it was possible to isolate the first-formed radioactive keratin with certainty and large differences were observed in the specific activity of the sulphur in the low-sulphur (fibrillar) and high-sulphur (matrix) proteins.

In the 'prekeratin' the specific activity of the sulphur in the high-sulphur protein is significantly higher than in the low-sulphur protein and this difference is greatly accentuated in the corresponding ratio for the keratoses from the keratin of the wool root residues. The reason for the smaller differences for the 'prekeratin' is probably due to the fact that wool roots as prepared include most of the developing fibre below the keratogenous zone[14] so that the urea extracts contain much of the newly formed fibrillar protein as well as matrix protein. Nevertheless the results support the mechanisms described by Rudall[3] and by Mercer[7] in which the high-sulphur proteins are synthesized at a late stage in the keratogenous zone of the follicle.

In conclusion, it would appear that the results of De Bersaques and Rothman[6] are in fact consistent with the mechanism for sulphur incorporation supported by the present results. Their results only require that some protein, not necessarily all the proteins in keratin, be synthesized in the keratogenous zone.

OCCURRENCE OF PSEUDO-BARBITURATES IN POST-MORTEM MATERIAL

By J. V. JACKSON and B. S. FINKLE

Metropolitan Police Laboratory, New Scotland Yard, London, S.W.1

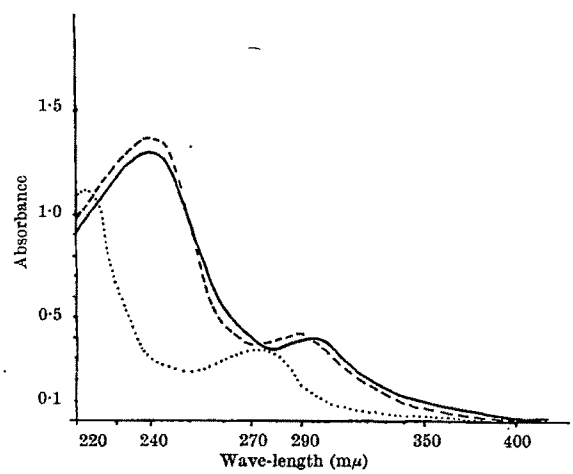
ON several occasions during routine toxicological analyses we have obtained unusual ultra-violet absorption spectra. These spectra have been observed on examining solutions of both the strong acid and barbiturate (weak acid) group residues, and have occurred after using direct ether or protein precipitation[1,2] extraction techniques. We have referred to them as 'pseudo-barbiturate' spectra because of their similarity, between wave-lengths 230 to 260 mμ, in dilute ammonia and acid, to the absorption curves of the barbiturates (Fig. 1). These pseudo-barbiturates have been noted in liver, kidney, muscle, blood and urine extracts, obtained from fresh, old and exhumed post-mortem specimens.

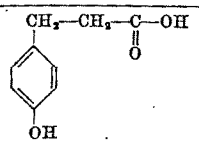
Most of these spectra have certain features in common:

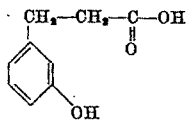
Solvent	Maxima
0·5 N NH_4OH	240, 292
Dilute H_2SO_4	275
0·5 N NaOH	240, 292

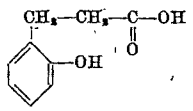
This basic pattern is shown in Fig. 1, but minor variations are sometimes observed, for example, an additional point of maximum absorption at 328 mμ in 0·5 N ammonium hydroxide and 0·5 N sodium hydroxide solutions is given by some extracts.

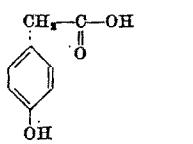
Ascending paper chromatography, using the *n*-butanol/ammonia[3] or amyl alcohol/ammonia[4] systems on Whatman No. 1 paper, of residues containing pseudo-barbiturates gave variable results. Both absorbing and fluorescent spots were visible under filtered ultra-violet light (2537 Å). The absorbing spots were not intensified by exposure to ammonia vapour and none of the spots gave a positive reaction with the cobalt chloride reagent[4], thus distinguishing them from genuine barbiturates. The ferric chloride/ferricyanide reagent[5], for phenolic compounds, reacted with most of these spots. Additional spots, not observed with ultra-violet light, were revealed by this reagent on some of the chromatograms. The chromatographic examination of these residues had therefore shown that we were dealing with a complex mixture of interfering chromogens.

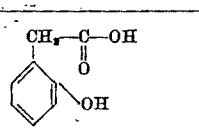


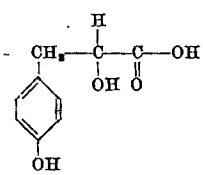












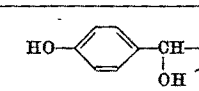


Fig. 1. Ultra-violet absorption spectrum of a 'pseudo-barbiturate' ····· *p*H 2; – – –, *p*H 10; ——, *p*H 13

One of the absorbing spots (R_F value 0·10, using the amyl alcohol/ammonia system) was consistently observed in chromatograms of material from old or exhumed viscera. This spot was eluted and identified by X-ray diffraction (Fig. 2) and infra-red absorption techniques (Fig. 3) as β-*p*-hydroxyphenyl propionic acid. The ultra-violet absorption spectrum of this compound gave a pattern identical with Fig. 1. This compound is known to occur in exhumed viscera[6,7] and has been suggested as a possible cause of interference with the ultra-violet spectrophotometric determination of barbiturates[8]. However, residues from fresh post-mortem samples also exhibiting a pseudo-barbiturate type spectra gave chromatograms without this particular spot. β-*p*-Hydroxyphenyl propionic acid is a degradation product of tyrosine[9]. Many other breakdown compounds of this amino-acid are known and could possibly be present in viscera. We have

Table 1. Ultra-violet Absorption Details of Compounds having 'Pseudo-Barbiturate' Type Spectra

Name	Structure	$E^{1\%}_{1\ cm}$				
		*p*H 10		*p*H 13		*p*H 2
		240 mμ	292 mμ	240 mμ	292 mμ	275 mμ
β-*p*-Hydroxyphenyl propionic acid		333	87	393	100	100
β-*m*-Hydroxyphenyl propionic acid		320	136	352	156	96
β-*o*-Hydroxyphenyl propionic acid		247	107	278	138	71
p-Hydroxyphenyl acetic acid		555	136	585	150	87
o-Hydroxyphenyl acetic acid		552	200	581	238	124
p-Hydroxyphenyl lactic acid		249	66	249	66	40
p-Hydroxyphenyl mandelic acid		200	48	200	48	33

measured the ultra-violet absorption spectra of some of these substances (Table 1) and have found that the particular pattern of Fig. 1 is common to many other phenolic compounds. We are therefore attempting to correlate these with the unidentified spots on the chromatograms.

Unusual ultra-violet absorption spectra have been previously described[10,11]. These also occurred in the acid ether extracts of post-mortem livers. Although the ultra-violet absorption spectrum of the interfering chromogen recovered by Curry[12] from fresh post-mortem liver specimens is identical with that of β-*p*-hydroxyphenyl propionic acid, the chromatographic behaviour is quite different. His unknown compound gave a spot, which had a blue fluorescence in ultra-violet light, near the solvent front, whereas β-*p*-hydroxyphenyl propionic acid gives an absorbing spot near the base line. It is interesting to note that one of our specimens of β-*p*-hydroxyphenyl propionic acid, originally synthesized in 1951 [6], now gives two spots when examined by paper chromatography and one of these is a fluorescent spot near the solvent front.

Another unusual spectrum was noted by Walls *et al.*[11] and afterwards identified as being due to a mixture of *p*-hydroxybenzaldehyde and *p*-hydroxy benzoic acid. *p*-Hydroxybenzaldehyde also gives a pseudo-barbiturate pattern plus an additional peak at 328 mμ. This may well explain one of the variations we have observed in our cases.

Ultra-violet spectrophotometric methods are widely used in clinical laboratories for the detection of barbiturate poisoning in patients, and many hospital biochemists are now undertaking the analysis of post-mortem specimens for barbiturates. In view of the possible occurrence of pseudo-barbiturates in post-mortem material we think it is important to emphasize that the detection of an absorption peak at 240 mμ (even when accompanied by a large optical density difference between *p*H 10 and *p*H 2) does not prove the presence of a barbiturate. This behaviour is characteristic of many other compounds. Further, the $E^{1\%}_{1cm}$ values of these pseudo-barbiturates is of the same order as genuine barbiturates. Thus, concentration of β-*p*-hydroxyphenyl propionic acid as low as 0·06 mg per cent will give an optical density reading of about 0·6 at

Fig. 2. X-ray diffraction pattern of β-*p*-hydroxyphenyl propionic acid

240 mμ. Measurement of the whole spectrum between 230 and 330 mμ is essential for the detection of these interfering compounds. Examination of the pseudo-barbiturate curve (Fig. 1) will show that the criteria mentioned by Broughton[13] are not fulfilled, therefore this spectrum could not be mistaken for a 5 : 5 di-substituted barbiturate spectrum. If only a limited portion of the spectrum is plotted, however, it may be mistaken for the curve of a 1 : 5 : 5 substituted barbiturate.

If both barbiturate and pseudo-barbiturate are present the only reliable method of assay is by eluting the barbiturate spot from a chromatogram and subsequent ultra-violet spectrophotometry.

We thank Dr. Ivor Smith and Dr. J. B. Jepson for providing us with samples of compounds involved in this work, and Mr. L. C. Nickolls for his encouragement and advice.

CYTOCHEMICAL DEMONSTRATION OF UBIQUINONES IN ANIMAL TISSUES

By J. P. TRANZER* and Dr. A. G. E. PEARSE
Department of Pathology, Postgraduate Medical School, London W.12

SUCCINATE dehydrogenase cannot be demonstrated histochemically in material embedded in paraffin wax[1]. Nor can it be demonstrated in freeze-dried blocks, or in air-dried cryostat sections, if these have been incubated for brief periods in low melting point waxes. While studying this enzyme inactivation we added a number of substances to the wax as anti-oxidants. We found that succinate dehydrogenase was apparently completely reactivated in cryostat sections incubated in wax to which a small quantity of hydroquinone had been added. Control tests showed that neither the wax nor the dehydrogenase was a contributory factor since fresh cryostat sections incubated in buffer containing only hydroquinone and our customary tetrazolium salt, 3-(4,5-dimethylthiazolyl-2)-5-diphenyl tetrazolium bromide (MTT), gave an equally strong reaction.

We considered and tested a number of different hypotheses before concluding that this reaction was due to ubiquinones and possibly closely related compounds. Our reasons for this conclusion form the first part of this paper and some results of the application of the method the second half.

Technical details of the reaction. The best results are given by the following technique. Fresh cryostat sections (8μ), dried in air at room temperature, are incubated in a medium composed of: 0·25 ml. MTT (1 mg/ml.) in distilled water; 0·05 ml. cobalt chloride (0·5 M); 0·40 ml. *tris* buffer (0·2 M, *p*H 7·4); 0·10 ml. hydroquinone (40 mg/ml., in *tris* buffer, *p*H 7·4); 0·20 ml. distilled water; 2 mg catalase.

Sections are incubated for 10–30 min at 37°. They are then fixed in 10 per cent formalin at room temperature for 15 min, and afterwards washed briefly in running water. After counterstaining the nuclei in 2 per cent chloroform-washed methyl green (2 min) the sections are rinsed in distilled water and mounted in glycerine jelly.

* British Council Scholar.

Hydroquinone. This solution must be absolutely fresh. The final concentration of 4 mg/ml. is that found to be best; but a concentration of 0·4 mg/ml. gives strong reactions in rat liver. Higher concentrations weaken the reaction.

*p*H. Below *p*H 5·2 the reaction is negative or very weak. Higher *p*H-levels than 7·4 were not tested because of their effect on reduction of tetrazoles by protein and carbohydrate tissue components.

Catalase. When the incubating medium (containing no catalase) is left in contact with glass or air, after a short period of time a black film of formazan appears. This spontaneous reaction is minimal at acid *p*H-levels, but so also is the histochemical reaction. The addition of catalase completely prevents the slow spontaneous reaction.

Other components. The concentrations of tetrazole, cobalt chloride and buffer are those used in present practice[2]. Cobalt (Co^{2+}) ions are chelated by the nascent formazan which is prevented thereby from crystallizing.

Alternative electron donors and acceptors:

Donors. Resorcinol, pyrocatechol, *p*-phenylene diamine, pyrogallol.

Acceptors. 2,2′-di-*p*-nitrophenyl-5,5′-diphenyl-3,3′-(3,3′-dimethoxy-4,4′biphenylene) ditetrazolium chloride (Nitro-BT). 2-(*p*-iodophenyl)-3-(*p*-nitrophenyl)-5-phenyl tetrazolium chloride (INT). 2,2′,5,5′-tetra-*p*-nitrophenyl-3,3′-(3,3′-dimethoxy-4,4′-biphenylene) ditetrazolium chloride (Tetra Bitro-BT). These were used in the same concentrations as the hydroquinone and the M.T.T., respectively.

Resorcinol and pyrocatechol give scarcely any spontaneous reaction with MTT and the former gives little reaction with the other tetrazoles. Pyrocatechol-MTT mixtures gradually darken but give no reaction in tissue sections. With *p*-phenylene diamine MTT gives a histochemical reaction, resembling that obtained with hydro-

quinone; but the presence of brownish decomposition products makes interpretation difficult. Pyrogallol reduces MTT spontaneously.

Tests of alternative tetrazolium salts as final electron acceptors showed that only tetra-Nitro-BT gave any immediate reaction with hydroquinone. Nitro-BT and INT gave a feeble reaction after long incubation. With pyrogallol tetra-Nitro-BT was reduced spontaneously, but Nitro-BT and INT gave a histochemical reaction broadly comparable with that shown with hydroquinone-MTT. Only the latter gave results which could be used for detailed investigation at the cytological level.

Influence of different factors on the reaction.

Action of fixatives: (*a*) *15 per cent formaldehyde.* Sections fixed for 5–60 min at room temperature gave reactions as strong as those of unfixed sections. (*b*) *1 per cent osmium tetroxide.* Sections fixed for 15 min at 4° in Palade's[3] medium showed complete inhibition of the reaction. (*c*) *Absolute ethanol.* Treatment for 1 h at room temperature completely abolished the reaction. (*d*) *Absolute acetone.* Similar treatment as with ethanol only slightly reduced the reaction.

Other organic solvents were tried. Chloroform produced complete inhibition; ether and petroleum spirit (b.p. 40°–60°) had little or no effect.

Action of heat. (*a*) *Dry heat.* Treatment at 90° for 30 min produced no change. (*b*) *Moist heat.* Treatment with water or 15 per cent formaldehyde at 90° for 30 min did not prevent the development of the reaction.

Addition of coenzymes. Addition to the hydroquinone-MTT medium of NAD, NADP or cytochrome *c* (2 mg/ml.) had no effect on the reaction.

Enzyme inhibitors. The following substances were added to the incubation medium at *p*H 7: potassium cyanide (0·01 M), 'Amytal' (0·01 M), 'Dicoumarol' (0·01 M), 'Phenindione' (sat. soln.), hydroxylamine (0·03 M), NaN_3 (0·03 M). Potassium cyanide was used in the absence of cobalt, with which it forms an unstable electron-donating complex. The reaction was affected only by sodium azide.

Possible mechanisms for the reaction

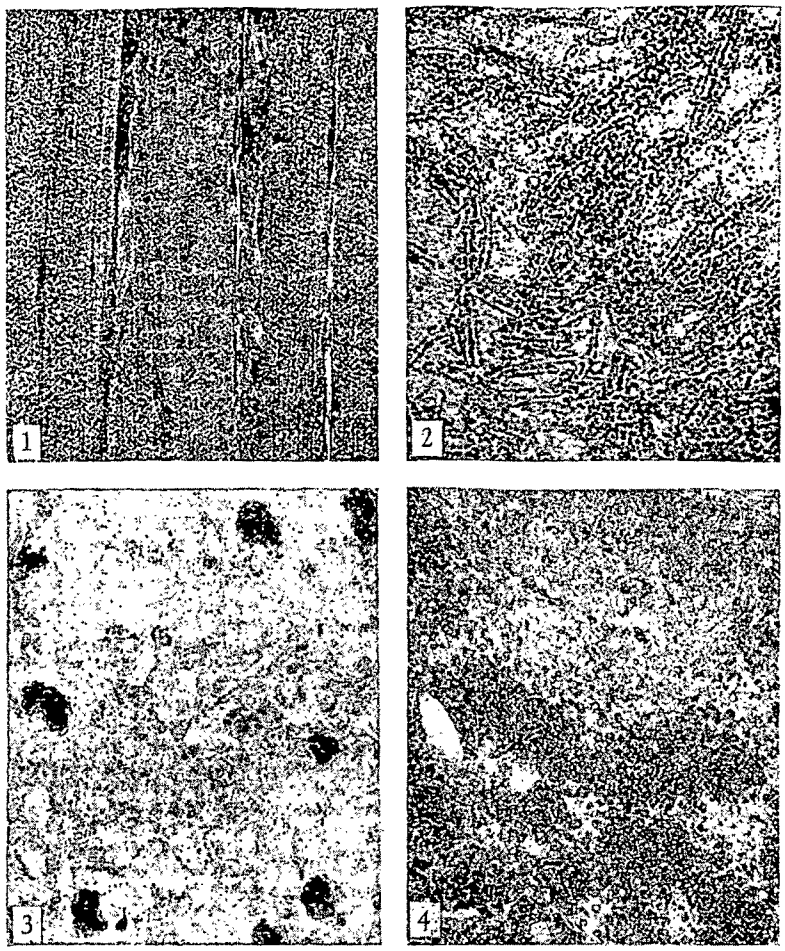
We considered a number of different hypotheses to explain our observations. These included physico-chemical artefact (adsorption of preformed formazan), non-specific enzyme activity, specific enzyme activity (hydroquinone dehydrogenase), and non-enzymatic catalysis.

Physicochemical artefact. The spontaneous reaction between hydroquinone and MTT, which occurs in the presence of air, at the surface of the medium, presumably occurs in the following manner:

$$1/2\ O_2 + H_2O \rightarrow H_2O_2$$

$$\text{Hq (hydroquinone)} + H_2O_2 \rightarrow \text{Q (quinone)} + H_2O + (O) + (2H).$$

$$\text{MTT} + (2H) \rightarrow \text{MTF (formazan)}$$



$$H_2O + (O) \rightarrow H_2O_2$$

In the presence of catalase hydrogen peroxide cannot exist and the foregoing reaction is therefore prevented. The cytochemical reaction, however, is not affected. On this evidence we rejected the first hypothesis altogether.

Enzyme activities. The cytological appearances of sections incubated in the hydroquinone-MTT medium appeared, at first sight, closely to resemble those obtained with techniques for succinate dehydrogenase and the two mitochondrial diaphorases. We were obliged, therefore, to investigate the possibility that enzyme activity might be responsible.

It is known that hydroquinone can be oxidized by tissue extracts such as the Keilin–Hartree heart muscle preparation[4,5]. Substantial results have been obtained, however, only after addition of cytochrome *c*. Among others Ogawa *et al.*[6] have shown that tetrazolium salts can accept electrons from different parts of the respiratory chain, including the region of cytochrome a^3, so that cytochrome oxidase could have been responsible, in theory, for the reaction. We considered, however, that its resistance to heat, formaldehyde and potassium cyanide, and the lack of effect from the addition of cytochrome *c*, must rule out the passage of electrons from hydroquinone to MTT by way of cytochrome oxidase.

It seemed possible that endogenous coenzymes such as NAD and NADP, reduced by hydroquinone, could transfer electrons by way of their respective diaphorases. This hypothesis was regarded as untenable, for various reasons. The oxidation-reduction potentials of the reactants are such that the reaction would proceed in the opposite direction to that required.

All photomicrographs are of 8μ cryostat sections, unfixed

Fig. 1. Rat; striated muscle. The distribution of ubiquinones is apparently sarcosomal (× *c.* 297)

Fig. 2. Rat; spermatozoon middle pieces. The product of the reaction is exclusively mitochondrial (× *c.* 776)

Fig. 3. Rat; intestinal lamina propria. Eosinophil leucocytes distinguished by a very intense reaction in their granules (× *c.* 776)

Fig. 4. Rat; lymph node. Above, large reticulum cells in a germinal centre show a strong non-mitochondrial reaction. Below, pyroninophilic plasmacytes show strong mitochondrial staining (× *c.* 136)

Hydroquinone E_0 = + 0·681 V (ref. 7)
NAD E_0 = − 0·113 V (ref. 8)

Furthermore, the concentrations of NAD and NADP in the tissues are very low and the addition of either coenzyme did not affect the reaction.

Hydroquinone itself might have been the substrate, transfering electrons by way of the diaphorases. We found, however, that no such transfer occurred when solutions of either bacterial diaphorase (Nutritional Biochemical Corporation) or a Straub diaphorase from heart muscle (courtesy of Dr. M. Dixon) were added to the medium. The further addition of $NADH_2$ produced immediate reduction of the tetrazole, in both cases, showing that the diaphorase remained active under the conditions of the experiment.

Since Agner[9] had shown that the 'M–Nadi reaction' was due to a peroxidase we investigated the possible role of the latter. Neither peroxidase nor catalase could produce the true reaction, but with catalase we noted inhibition of the spontaneous reaction which has been referred to already.

After dismissing the non-specific enzmye activities detailed here we postulated the intervention of 'hydroquinone' dehydrogenase. Enzymes of this type, the laccases, have been described in plants and lower organisms[10–12]. They have not been described in animal tissues, and would, in any event, have difficulty in surviving the strenuous inactivation procedures which we used. We were finally obliged, therefore, to consider the participation in the reaction of a non-enzymatic catalyst.

Catalysis by ubiquinones.

In our search for a possible catalyst or intermediate substance we tested once more the effect of alcohol in inactivating the reaction. Pieces of rat liver (about 1·5 g each) were freeze-dried in an apparatus recently described[10–12]. The dried tissue was powdered and extracted with 4 ml. ethanol for a few hours at room temperature. After centrifugation, some drops of the supernatant were placed on a cover-slip and the ethanol allowed to evaporate. The dry residue, immersed in a fresh hydroquinone-MTT solution, rapidly became black. Our 'inactivation' was thus shown to be extraction.

The observed properties of our 'catalyst' appeared to resemble those of the ubiquinones described almost simultaneously by Morton *et al.*[14,15] and by Crane *et al.*[16]. Table 1, shows the comparison.

Ubiquinone-6 (Q30) (L. Light and Co., Colnbrook, Bucks) was dissolved in ethanol. One drop (containing approximately 50 γ) was added to 2 ml. of the hydroquinone-MTT medium and incubated at 37°. Rapid reduction of the tetrazole occurred with deposition of the black formazan. No reaction occurred with menadione (vitamin K_3) or with various sterols, including dehydroisoandrosterone, ethenyl œstradiol, œstradiol, and 17*a*-ethenyl-D5-anterosten-3*b*l7*b*-diol.

We have concluded, on the foregoing evidence, that the cytochemical reaction described in this article is due to the presence of ubiquinones. We have not excluded, however, the possibility that closely related compounds, such as vitamins K_1 and K_2, may be capable of giving a positive reaction. Mitochondria from animal sources, however, contain very little vitamin K. Measurements of the sensitivity of the reaction have yet to be made. Its catalytic nature leads one to suppose that this may be very high indeed.

Table 1

Tissue component giving reaction	Ubiquinone (ref. 17)
Oxidation–reduction catalyst	Oxidation–reduction catalyst; coenzyme of flavoproteins
Oxidation–reduction potential intermediate between hydroquinone and MTT	E_0 = 0·542 E *p*H 7·3 = 0·089
Reduced form can reduce tetrazoles	Coenzyme Q10 acts as intermediate electron transfer agent in succinate tetrazolium reductase systems (refs. 18, 19). Reduced CoQ reduces INT (ref. 17, p. 379)
Detectable cytochemically in the majority of mammalian tissues	Found biochemically in most mammalian tissues—hence the name ubiquinone (ref. 14)
Cytochemical localization predominantly mitochondrial	Mitochondrial preparation rich in ubiquinones
Cytochemical reaction not affected by water or aqueous solutions	Insoluble in water
Cytochemical reaction stable to heat up to 90°	Stable at 90°
Extractable from sections by ethanol and certain fat solvents. Fraction extracted rich in lipids	Extractable from homogenates by ethanol/ether 3 : 1. Purification by various fat solvents. Ubiquinones soluble in lipids

It may be predicted that by selection of a suitable primary electron donor, and of a suitable tetrazolium salt as final acceptor, it will be possible to demonstrate the localization and level of a number of redox substances, making use of their activity as intermediates.

Mechanism of the reaction.

The system involved is formed by three redox couples

(*a*) Hydroquinone $\underset{+2e}{\overset{-2e}{\rightleftharpoons}}$ Quinone
E_0 = 0·68 V at 25° (ref. 7)
E_0 *p*H 7·3 = 0·273 V at 25° (ref. 20)

(*b*) Ubiquinol $\underset{+2e}{\overset{-2e}{\rightleftharpoons}}$ Ubiquinone
E_0 = 0·542 V (ref. 21)
E_0 *p*H 7·3 = + 0·089 V (ref. 17, p. 170)

(*c*) Formazan $\underset{+2e}{\overset{-2e}{\rightleftharpoons}}$ Tetrazolium
$E\frac{1}{2}$ *p*H 7·2 = − 0·11 V at 22° (ref. 2, p. 537)

(*a*) and (*b*) are reversible in aqueous media and in organic solvents. (*c*) is reversible in organic solvents, but will not proceed from left to right in aqueous media, where the formazan is insoluble.

The available data on redox potentials are incomplete and not strictly comparable, since they have been obtained under very different conditions. For system (*c*) only polarographic data have been published. Nevertheless, it is considered permissible to compare polarographic with potentiometric measurements[22].

If the two couples (*a*) and (*c*) are in a condition of reversibility, and if the concentrations of their oxidized and reduced forms are correct, electrons should be transferred from (*c*) to (*a*). In aqueous media (*c*) is not reversible, however. Furthermore, in the Hq/MTT solution there is an excess of the reduced form of (*a*) and of the oxidized form of (*c*). This should favour the passage of electrons from (*a*) to (*c*). That such a transfer does not occur spontaneously may be explained by the close agreement between the two redox potentials.

The role of couple (*b*) appears to be that of an intermediate or catalyst. It has been observed that ubiquinol (the reduced form of the catalyst) can reduce certain tetrazoles directly[18,19] and pyrogallol, the E_0 of which is 0·713 (ref. 22) can reduce ubiquinone[17]. It is therefore probable that hydroquinone, which has a similar redox potential, can function in the same way. As already mentioned, we observed a positive reaction when we substituted pyrogallol (and Nitro-BT or INT) for hydroquinone and MTT.

The cytochemical results are not dependent solely on the different redox potentials of the tetrazolium salts used but also on their solubility in lipids, their substantivity for proteins and, probably, their stereochemical characteristics. The very much better results obtained with MTT must be ascribed mainly to its lipid solubility, since it is in the lipid phase that the whole reaction occurs.

Localization of ubiquinones in animal tissues.

Our present survey has been confined to rat and human tissues. The results are presented here in abbreviated form, emphasizing only points of special interest. In general the reaction was stronger in rat tissues than in human material. As expected, ubiquinones appeared to

be present in the majority of tissues and the intensity of the reaction was comparable with the levels found by other workers using biochemical assays. The reaction was predominantly mitochondrial (Figs. 1 and 2), but in some cells, such as those of the exocrine pancreas and of the serous salivary glands, an extramitochondrial reaction was observed. In the proximal convoluted tubules there was also a non-mitochondrial reaction, located at the luminal border of the cells or in the brush border. This suggested that the product made visible was in process of excretion in the urine.

In both man and the rat, an outstanding localization of ubiquinones is in the granules of the eosinophil leucocytes (Fig. 3). Even with short incubation the reaction is intense. Since electron microscopic studies[23,24] have shown that eosinophil cell granules contain a central osmiophilic crystalloid body it is probable that the ubiquinones are located in this (lipid) region. Electron cytochemical studies should resolve the problem. Speculation as to the possible functions of the eosinophil with respect to ubiquinones must include: (1) a high rate of synthesis, accompanied by storage; (2) absorption and storage; (3) transport to areas with high requirements for the coenzyme; (4) utilization for anabolic or catabolic processes.

In the reticuloendothelial system of the rat the Kupfer cells contain a few discrete granules of reaction product, but in some large reticulum cells, in the germinal centres and sinusoids of the lymph nodes, there are accumulations of large granules which are manifestly not mitochondrial. These reticulum cells are not pyroninophilic, but an equally intense reaction for ubiquinones occurs in cords of cells surrounding the sinusoids (Fig. 4). These cells stain strongly with pyronin, and the majority can be classified as plasma cells or their immediate precursors. Mast cells are usually negative for ubiquinones but occasionally, in the lymph node capsule, some strongly reacting examples can be seen.

Strongly positive reactions are characteristic of epithelial cells, both glandular and otherwise, and in these the product is mainly or exclusively mitochondrial. Because of reports that ubiquinone levels in tumours were found to be lower than those of normal tissues[17] we investigated the matter. It seems that in many epithelial tumours the ubiquinone level per cell is as high as it is per cell in the parent tissue. In some metastases, on the other hand, the levels per cell are below those per cell of the parent tumour. Mesenchymal tumours have low ubiquinone levels (and incidentally low levels of most mitochondrial oxidative enzyme systems). The level of ubiquinone in tumour cells probably does not merely reflect the number of mitochondria in the cell though there is obviously a relationship to this.

We have the impression that ubiquinone levels are high in cells concerned primarily with protein synthesis, whether this protein is designed for self-perpetuation or for export.

Applications of the hydroquinone-MTT reaction.

In addition to its use as a qualitative or semiquantitative cytochemical reaction, the possibility of developing a fully quantitative cytochemical technique can be considered. This would depend on the establishment of the stoichiometry of the reaction as has already been done for $NADH_2$ oxidation with menadione as intermediate electron carrier[25].

In vitro estimation of ubiquinones is also a distinct possibility. The reaction can be carried out with an alcoholic solution of the quinone and an aqueous Hq-MTT solution.

We have been able to show, using low concentration spots on filter paper, that the reaction is fully sensitive enough to be used for chromatographic recognition of ubiquinones. Further developments along these lines are planned.

5-HYDROXYTRYPTAMINE IN THE SPERMATOPHORIC SAC OF THE OCTOPUS

By Dr. T. MANN, C.B.E., F.R.S.

Institute for Space Biosciences, Florida State University, Tallahassee, and Agricultural Research Council, Unit of Reproductive Physiology and Biochemistry, University of Cambridge

THE male octopus, in common with other Dibranchiata belonging to the advanced molluscan class of Cephalopoda, possesses a single testis; this oval, whitish organ occupies together with the remainder of the reproductive tract (Fig. 1) a dorsal position in the visceral cavity and is attached to the cœlomic wall by a mesenteric fold of the peritoneum.

On leaving the testis the spermatozoa enter the long convoluted vas deferens through a slightly enlarged portion known as the ampulla, and from there pass into a thick-walled helically wound tubular gland, named by its discoverer de Cuvier[1], glandula vesicularis ('seminal vesicle'), and later examined by Marchand[2], Belonoschkin[3] and others. In the seminal vesicle the spermatozoa are enfolded by the glandular secretions into tube-shaped membranes and ultimately encased into the spermatophores. That task is performed by the seminal vesicle together with another closely located accessory gland, namely, the 'prostata' of de Cuvier, where the assembly of spermatozoa into the spermatophores is brought to completion. The seminal vesicle and prostate together constitute the so-called spermatophoric gland. Emerging from the prostate the spermatophores, each carrying numerous encased spermatozoa, pass along the vas efferens, sometimes also referred to as the distal vas deferens, into the capacious storage organ known after its discoverer in the eighteenth century, as Needham's sac, or simply the spermatophoric sac.

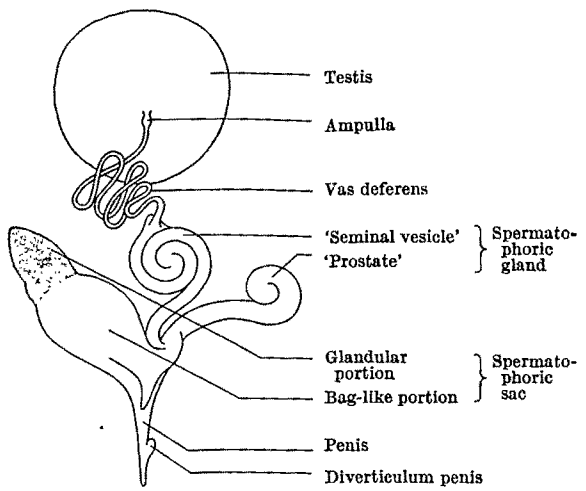

Fig. 1. Diagrammatic outline of the male reproductive tract (unravelled) of *Octopus vulgaris*, to illustrate the localization of 5-hydroxytryptamine (serotonin) in the glandular portion of the spermatophoric sac (Needham's sac)

On close inspection, Needham's sac of the octopus can be seen to consist of two distinct portions, one proximal to the efferent duct, shaped like a pouch or bag, and serving as a reservoir for the spermatophores, and another, more distally located, in appearance a secretory gland rather than a bag. The spermatophores lie in the bag-like portion in a match-box arrangement, all pointing outward with the same end. From the spermatophoric sac they are discharged into the penis, whence at the time of mating they are removed by one of the eight arms of the male octopus, the hectocotylized arm, to be transferred bodily into the mantle cavity of the female. The stimulus necessary for the discharge of the spermatophores is unknown; presumably it is furnished by the contraction of the spermatophoric sac itself, under the influence perhaps of a chemical stimulant. The lack of data in this respect prompted me to examine chemically the spermatophoric sac in *Octopus vulgaris*.

During a recent stay in the laboratory of Dr. Charles B. Metz, at Florida State University, I had the opportunity of examining the male reproductive tract in five specimens of *Octopus vulgaris*, caught in the Gulf of Mexico during February and March 1963, two of them small and three large, 0·5–2 kg in weight. A search was made in the various parts of the reproductive tract for substances known to be secreted by the male accessory glands in other animal species[4], including 5-hydroxytryptamine (serotonin, enteramine). I have shown earlier that this aromatic amine, which is capable of exerting a powerful stimulating effect on the uterus and other smooth-muscle organs, occurs in the secretion of at least one male accessory organ of aquatic animals, namely, the clasper-siphon sac of the spiny dogfish, *Squalus acanthias*[5]. An indole base, probably related to 5-hydroxytryptamine, which causes contractions of the oviducts of insects, has also been located in the male accessory secretions of certain insects such as *Rhodnius prolixus* and *Periplaneta americana*[6]. In mammals, on the other hand, no unequivocal evidence has as yet been obtained for the occurrence of 5-hydroxytryptamine in either whole semen or in the secretions of male accessory organs of reproduction[7].

The chemical analyses carried out on the two portions of Needham's sac separately have shown that the glandular portion of the spermatophoric sac, in distinction to the bag itself, contains a remarkably high concentration of 5-hydroxytryptamine, and that it also produces smaller quantities of at least one and possibly two other diazo-reactive and ultra-violet-absorbing substances. This demonstrates for the first time the presence of 5-hydroxytryptamine in the male genital tract of the octopus. The other organ of that animal in which the same indole base had previously been shown to occur is the posterior salivary gland[8].

Quantitative analysis of 5-hydroxytryptamine in the spermatophoric sac (glandular portion) of the five animals examined, based on the reaction given by that base with 1-nitroso-2-naphthol[9], gave values ranging from 12 mg/100 g tissue (fresh weight) in the smallest specimen to 169 mg/100 g in the largest one. The identity of the indole base was confirmed as follows. The spermatophoric sacs of the three large animals, totalling 9·6 g, were extracted by grinding with 70 ml. ethanol, the centrifuged ethanolic extract was evaporated to 5 ml., centrifuged, reprecipitated with equal volume of ethanol, centrifuged again, and the colourless water-clear solution (10 ml.) was analysed by three methods: spectrophotometrically, spectrophotofluorimetrically, and chromatographically. The ultraviolet spectrum measured in the Beckman recording spectrophotometer showed an absorption maximum at 273 mμ, and on addition of 0·04 N sodium hydroxide exhibited a small subsidiary absorption maximum at 325 mμ. Taking the optical density observed and the molecular extinction coefficient $\varepsilon = 5{\cdot}3 \times 10^3$ (at 275 mμ), the content of 5-hydroxytryptamine was calculated as 10·1 mg/10 ml. extract or 105 mg/100 g tissue. The fluorimetric analysis was carried out in the Aminco–Bowman spectrophotofluorimeter, in the presence of 3 N hydrochloric acid and 0·003 per cent ascorbic acid (activation maximum at 295 mμ; fluorescence maximum at 540 mμ). It gave a value of 9·2 mg 5-hydroxytryptamine in 10 ml. extract. Chromatograms were run at room temperature for 16 h on Whatman No. 1 paper, with butanol/acetic acid and *n*-propanol/acetic acid as solvents. On spraying with Ehrlich's reagent[10] and diazotized sulphanilic acid[11], a characteristic spot was revealed, with an R_F value identical with that of pure 5-hydroxytryptamine creatinine sulphate.

The demonstration of a large amount of 5-hydroxytryptamine in the Needham's organ of the octopus not only establishes the occurrence of that pharmacologically active amine as a normal constituent in the male genital tract of a mollusc, but also helps to bring out an interesting, hitherto unsuspected, chemical difference as between the glandular and the reservoir portion of the spermatophoric sac (Fig. 1). It also suggests that in the octopus, in any event, serotonin may play a part in the ejaculatory process. This might perhaps be envisaged as an induction of either the discharge of the spermatophores from the spermatophoric sac, or a stimulation of contractions within the male or female reproductive tract, assisting the passage of spermatozoa to the site of fertilization.

This investigation (Contribution No. 12 of the Institute for Space Biosciences) was supported by the National Aeronautics and Space Administration (*NsG*–173–62) and the U.S. National Science Foundation (*G*–9150). It was initiated during my stay as visiting professor in biology at the Florida State University, and continued at the University of Cambridge. I thank Dr. C. B. Metz and Dr. S. Fox for generously placing laboratory facilities at my disposal, and Mr. D. Hampson and Mr. J. Couch (Tallahassee), and Drs. D. F. Sharman and R. F. Seamark (Cambridge) for assistance.

A MOLECULAR THEORY OF MUSCLE CONTRACTION: CALCIUM-DEPENDENT CONTRACTIONS WITH HYDROGEN BOND FORMATION PLUS ATP-DEPENDENT EXTENSIONS OF PART OF THE MYOSIN-ACTIN CROSS-BRIDGES

By Prof. R. E. DAVIES

Laboratories of Biochemistry, Department of Animal Biology, School of Veterinary Medicine, and Graduate Group on Molecular Biology, University of Pennsylvania, Philadelphia, Pennsylvania

ENOUGH new information has become available recently to permit the development of a molecular theory of muscle contraction based on a reasonable sequence of known chemical reactions.

(I) Basis

This theory rests on the following observations and conclusions.

(1) Electron micrographs of fixed, stained, mammalian, skeletal muscles show that the actin and myosin are arranged as in Fig. 1. The thick filaments of myosin are in the central region of the sarcomeres, and have a six-fold screw axis of symmetry with a helical arrangement of the cross-bridges which contain the *H*-meromyosin ATPase. The *F*-actin filaments are attached to the *Z*-lines between each sarcomere, and can link with three thick filaments[1]. They are composed of an open double helix with 13 sub-units (*G*-actin) in each turn of each helix[2].

(2) The individual myosin molecules in the myosin filaments are oriented in opposite directions on either side of the centre of the filaments. The actin filaments are structurally polarized in opposite senses on either side of the *Z*-lines. This ensures that the individual filaments slide in one direction only during contraction[3].

(3) The interdigitating-filament mechanism represents essentially the anatomical description of contraction, that is, the thin filaments move along the channels between the thick filaments without overall changes in length. The ends of the muscle thus get nearer as in a collapsing telescope[1,4] (Fig. 2).

(4) When muscle is activated, calcium is apparently released from the vesicles of the sarcosplasmic reticulum into the cytoplasm, and is later removed by the action of the 'relaxing-factor' system[5].

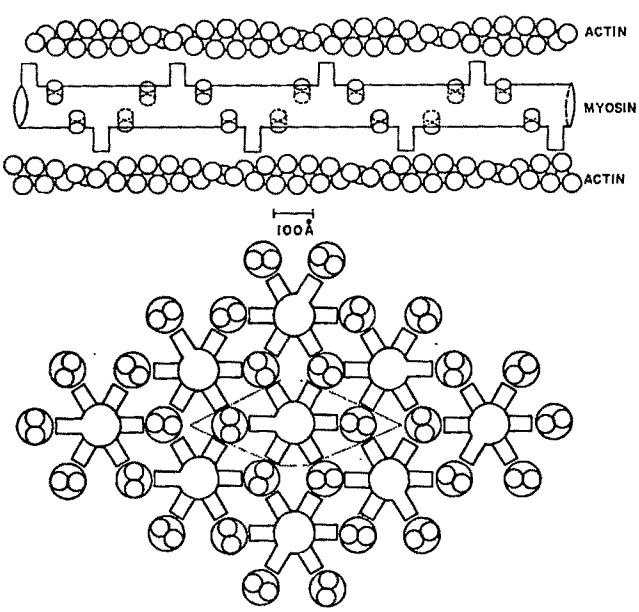

Fig. 1. Spatial arrangement of myosin and actin filaments in fixed striated muscle (rabbit psoas)

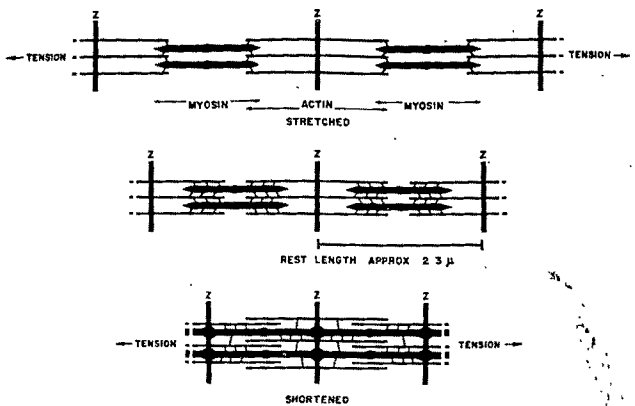

Fig. 2. Schematic diagram of contraction of skeletal muscle showing some completed cross-bridges at various lengths

(5) Tension development, shortening and work follow from the periodic making and breaking of cross-links between the myosin cross-bridges and the receptor sites on the actin[1,2,4].

(6) Adenosine triphosphate (ATP) is broken down both during smooth tetanic contractions and during single twitches. It is normally regenerated by ATP–creatine phosphoryl transferase and by myokinase during the rising phase of contraction. The net amount of 'high-energy' phosphate compound used is largely related to the work done by the muscles and, to a lesser extent, to the process associated with the active state[6].

(7) During the contraction cycle the actin of muscle remains in the form of double helical *F*-actin containing one bound ADP per *G*-actin sub-unit. This ADP is probably bound via calcium[2,7].

(8) The myosin filaments have one firmly bound ATP per H-meromyosin cross-bridge, and this ATP has a small but finite chance of dissociating[1,8]. It can be cleaved to ADP when it gets close to the *H*-meromyosin ATPase. The ADP formed can be rephosphorylated by, or exchanged with, free cytoplasmic ATP. The observed action of myokinase during a single contraction of frog muscle proves that this overall reaction must occur several times during the time the work is being done[6].

(II) Assumptions

The theory is based on the following assumptions.

(1) The binding site for ATP is at the end of a mobile polypeptide which is part of the *H*-meromyosin cross-bridge (Fig. 3). The bound ATP is electrostatically held by three positive charges which are probably three magnesium ions forming electrostatic links with negative groupings on the protein (cf. ref. 9).

(2) There is a fixed negative charge (perhaps phosphoryl-serine) inside the *H*-meromyosin cross-bridge and near the mobile polypeptide (Fig. 3) which repels the extra negative charge of the ionized ATP so that in the resting state the asymmetrically arranged polypeptide chain is on average extended (see section IV, 5).

(3) When the muscle is activated the depolarization of the sarcolemma and the sarcoplasmic reticulum liber-

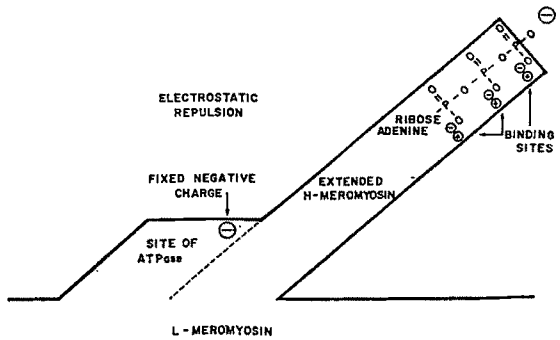

Fig. 3. Resting extended state. ATP bound to *H*-meromyosin

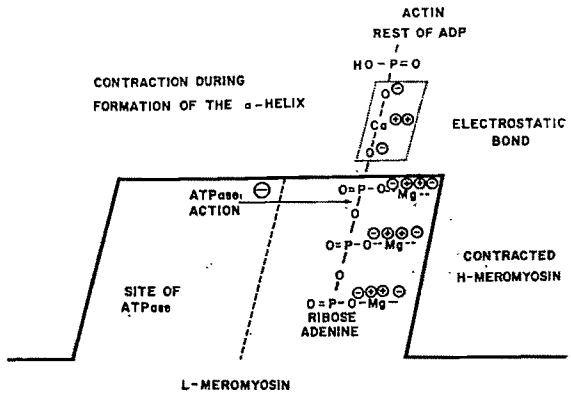

Fig. 5. Contracted *H*-meromyosin maintaining tension between itself and the bound ADP of actin

ates enough calcium to form chelate links between the bound ATP of the extended *H*-meromyosin polypeptide and the bound ADP of the *F*-actin (ref. 10) (Fig. 4). This step results in the formation of electrostatic bonds between the thick and thin filaments of the sarcomere, and by this fact causes the neutralization of the negative charge on the terminal phosphate and the abolition of the coulombic repulsion within the *H*-meromyosin. Thus the extended polypeptide in the cross-bridge contracts and forms an *a*-helix by twisting and forming hydrogen and hydrophobic bonds as in the elastic recovery of stretched *a*-keratin[11,12]. This process develops tension and, if the sum-total of the forces developed at any time by these ultramicro-contractions is sufficient to overcome the external load and the resistance of the series elastic elements, the actin filaments will be pulled along the myosin filaments into the A band and the muscle will undergo a quantal contraction (Fig. 4).

(4) The ATPase activity of the *H*-meromyosin cross-bridge is inside the cross-bridge and the active site does not have easy access to free cytoplasmic ATP. The contraction of the polypeptide chain brings the bound ATP into the region of activity of the *H*-meromyosin ATPase which then hydrolyses the ATP and breaks the link between myosin and actin[12] (Figs. 4–6). In the next step, the ADP bound to the cross-bridge is phosphorylated by cytoplasmic ATP in a process which probably requires magnesium. There could also be a slow exchange of the ADP with cytoplasmic ATP and this as well as 'product inhibition' could account for the inhibition of myosin ATPase by ADP (ref. 13). The change from ADP to ATP of necessity recreates the intense coulombic repulsion between the two negative charges so that part of the *H*-meromyosin is actively extended asymmetrically towards and along the nearby actin filament.

(5) The whole process repeats itself while calcium is available in the sarcoplasm (Fig. 4). The end of the 'active state' is taken to be the time when all the calcium has been pumped back into the sarcoplasmic reticulum by an active transport process which itself depends on ATP (relaxing factor)[5]. This requires that in the absence of stimulation the avidity for calcium is in the order: free solution < myosin ATP < inorganic phosphate in solution < ATP in solution ≈ link between actin ADP and inorganic phosphate < link between myosin ATP and actin ADP < sites for calcium in the sarcoplasmic reticulum. This sequence is reasonable on the basis of the apparent stability constants found by Smith and Alberty[14], and would result in low myosin ATPase activity at cross-bridges in regions where the myosin and actin filaments do not overlap, since the calcium would associate with the inorganic phosphate or ATP in solution rather than with the myosin ATP with its single free negative charge (see Section II, 1 and Fig. 5).

(III) Qualitative Conclusions

As has already been shown by A. F. Huxley[4], H. E. Huxley[1], Goodall[15], and Spencer and Worthington[15], many observations on muscles can be fitted to the inter-

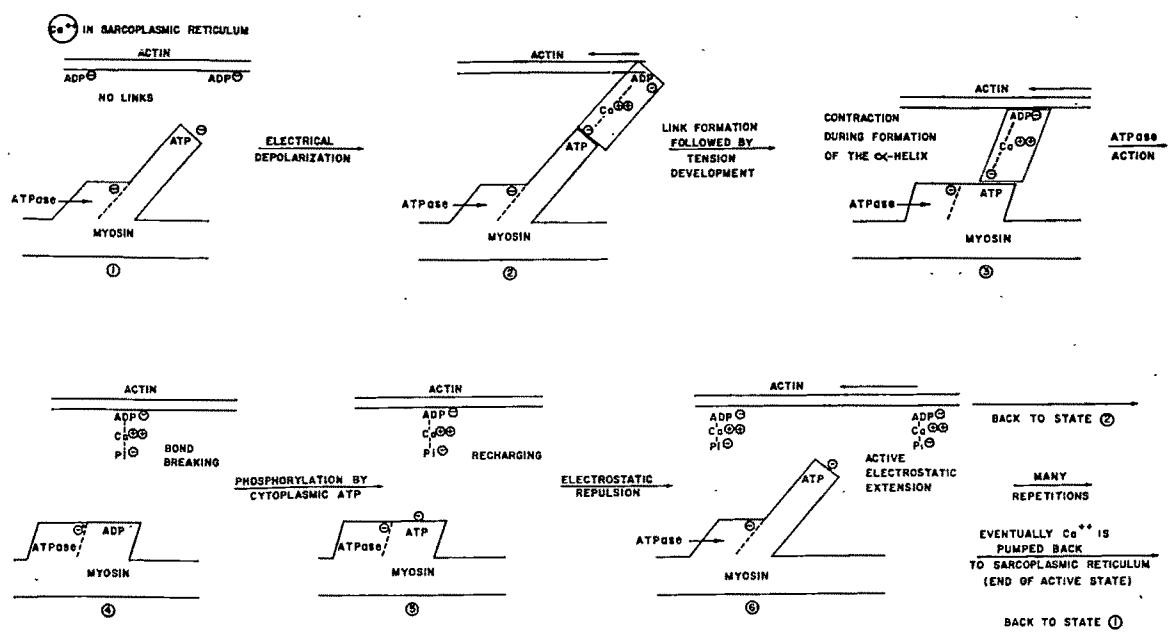

Fig. 4. Ca^{++}-dependent contraction during *a*-helix formation plus ATP-dependent extension of the cross-bridges

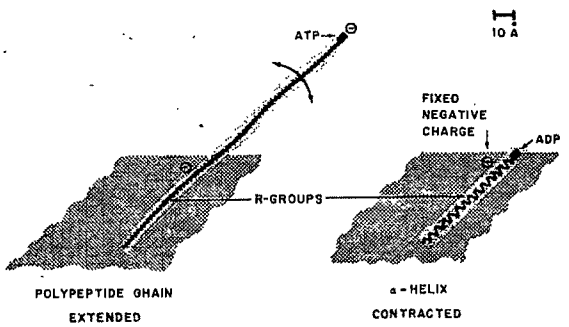

Fig. 6. Diagram of a flexible polypeptide chain of an *H*-meromyosin in the extended and contracted state

digitating filament theory of muscle contraction in which the chance of a local reaction between the myosin and actin filaments is inversely proportional to a function of the relative velocity of the filaments. These include: (1) the early increase in torsional rigidity; (2) the Hill equation relating force and velocity; (3) the loss and redevelopment of tension during 'quick release' of an activated muscle. The length-tension diagram has been explained by A. F. Huxley and H. E. Huxley as follows[1,4]. Tension is low at extreme lengths because the region of overlap of all the filaments is reduced and low at short-lengths both because the myosin filaments hit the *Z* lines and crumple, and because they are pushed apart laterally by the overlapping of the actin filaments which reduces the chance of link formation. Calculations of the rate of turnover of ATP necessary to drive such a model have been shown to be entirely reasonable on the basis of the enzyme activity in extracts of muscle[1].

The principle of the detailed theory presented here has some similarities to the possibilities put forward by Meyer[16], and Morales, Botts, Blum and Hill[16], and also to the explanation of the movement of the entropic-mechanochemical filaments of Kuhn[16]. However, only part of the cross-bridges are involved in the electrostatic extension and, in contrast to their views, the subsequent contraction causes a decrease of configurational entropy in the polypeptide chain. The energy for contraction comes from the formation of numerous hydrogen bonds which had been previously split by the action of ATP. These reactions could be part of the 'thermo-elastic' effect which is believed to account for the 'heat burst' during a 'quick release'[17], and the reversal of these reactions, as the peptides extended simultaneously, could be part of the absorption of heat during the subsequent spontaneous redevelopment of tension[17] (cf. Section IV, 6). The appearance of these reactions in activated muscles may well account for the apparent change in the thermo-elasticity of muscle from rubber-like when resting to steel-like when active[17].

The theory provides ready specific explanations for several other events occurring in muscle and leads to several predictions. These include:

(1) The amount of calcium that must be micro-injected into muscle to cause maximum contraction should be equal to at least the number of cross-bridges (see Section IV, 1).

(2) The length of the latent period should be the time needed for the calcium to get out from the sarcoplasmic reticulum to the sites where it links the actin and myosin and for the links to be formed (see Section IV, 2).

(3) The early increase then decrease in volume, and latency relaxation[18] are of the right order of magnitude to be manifestations of the expected changes in partial molal volume (compare ref. 19) associated with the differences in electrostriction between the states of the calcium tightly bound in the sarcoplasmic reticulum, in free solution in the sarcoplasm, and in the postulated bond between the nucleotides. Later volume changes can be associated with the splitting of ATP and phosphoryl-creatine, and with lactic acid formation[18].

(4) The increase of resistance to passive stretch[20] is associated with the formation of the calcium chelate links and occurs before contraction begins.

(5) Activation heat is a manifestation of the heat of dissociation of the calcium from its very firmly bound state in the sarcoplasmic reticulum. This follows depolarization and begins before tension development occurs (see Section IV, 3). It is little influenced by the length of the muscle. The heat uptake on forming the chelate links would be swamped by the output caused by the immediate contraction of the polypeptide (Section IV, 6). Work is needed later to pump back the calcium into the sarcoplasmic reticulum (see Section III, 9).

(6) The maintenance of tension would not *per se* require much ATP breakdown. This might explain the ability of some smooth muscles to remain in tension for very extended periods with only a small output of metabolic energy[21,22] (cf. Section III, 17).

(7) ATP and phosphorylcreatine breakdown are mainly associated with work[6,23]. ATP is broken down only if movement of the cross-bridges can occur. Since more links are formed and broken in a given time and over a given distance at low speeds of shortening with heavy loads than at high speeds with light loads both external work and power development depend on ATP splitting.

(8) In isometric contractions in fully pre-shortened and fully pre-extended muscles not much movement can occur and no significant ATP breakdown is detectable in rectus abdominis muscles with present techniques[24]. In any event, the work associated with any such movement would be low[25]. In maintained isometric tetani around rest length, micro inward movements and subsequent slippage of individual actin filaments could occur continuously since some filaments would have more and some less than the average muscle tension per square centimetre. Thus some ATP breakdown would be expected and does occur[24].

(9) The biochemical equivalent of the activation heat should be associated with the activity of the calcium pump which transports the calcium back into the sarcoplasmic reticulum[5]. The breakdown of 'high-energy' phosphate associated with this endothermic calcium binding (cf. Section IV, 3) would thus be delayed and seen during relaxation[6]. It is of the right order of magnitude to account for the expected amount of calcium involved (see Section IV, 1).

(10) In hypertonic solutions contraction fails or becomes very slow. It is known that the helical content of copoly-L-lysine-L-glutamic acid (1 : 1) is quite dependent on, and increases with, ionic strength. Such an attenuation of the electrostatic interactions of the charged groups would reduce the statistical length of the *H*-meromyosin polypeptide until it could not, or only occasionally, reach to the actin[26].

(11) 'Shortening heat'[17,27] is identified with the heat of formation of many hydrogen bonds during only the first contraction of each of the originally extended polypeptide chains (Figs. 4 and 6). This will continue during the creeping of the ends of the actin filaments along the myosin filaments as they form new links with each of the cross-bridges that they reach. This will be largely independent of length and load (but see Section IV, 6). Complete cyclic formation and breakage of the hydrogen bonds in the periodic contraction-extension steps will be thermally neutral, but during the decay of the active state all the chains will become re-extended with breakage of the hydrogen bonds. This will cause a heat absorption just equal to the earlier shortening heat because of the large increase in entropy. However, there is no net absorption of heat because of the larger heat output from the concomitant overall biochemical changes in the working muscle.

This reconciles Hill's observation of a shortening heat in moving, fully activated muscles with the absence of

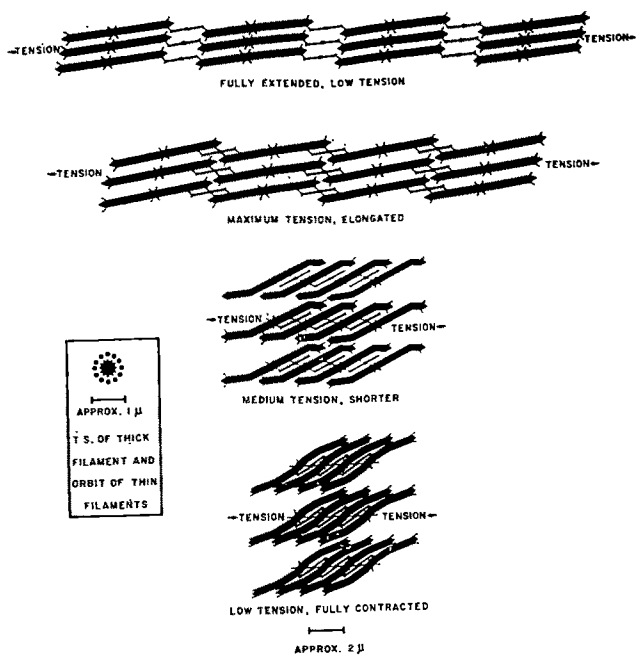

Fig. 7. Schematic diagram of contraction of smooth muscle (translucent adductor of oyster) showing some completed cross-bridges and developed tension at various lengths

such shortening heat in the complete cycle of contraction and relaxation in muscle twitches as found recently by Carlson, Hardy and Wilkie[23] (see Section IV, 6).

(12) Muscles in which most of the ATP has been broken down, and glycerinated muscle models in which the ATP but not the actin-bound ADP has been leached out, are in rigor and are stiff[28]. This is expected since the positive binding sites on the *H*-meromyosin would be strongly attracted to the actin ADP and the fixed negative charge of the *H*-meromyosin. The extended polypeptide would contract, actomyosin would be formed, and the whole system would become rigid. The addition of pyrophosphate, or ATP plus an ATPase inhibitor, plasticizes the muscle models in the presence of relaxing factors[28]. This latter would create state 1 of Fig. 4 with the actin and myosin repelling each other.

(13) Myosin ATPase requires magnesium and is strongly activated by calcium and by calcium plus actin, and there is an initial burst of ATPase activity[1,28,29]. This follows from Figs. 4 and 5.

(14) Relaxing factor is believed to operate by removing calcium from effective contact with the actin and myosin. Relaxation, or reduction of tension, also occurs on addition of excess ATP to muscle models. This would bind calcium and magnesium and tend to remove them from the myosin–actin link[5,26].

(15) The persistence of tension on stretching an activated muscle[1] is expected. The links would have less chance to be detached by the ATPase since the *H*-meromyosin polypeptide could not contract.

(16) The apparent 'disappearance' of energy during the forcible stretching of activated muscle[27] is identified as a reversal of the heat of formation of many hydrogen bonds during only the first extension of the largely contracted tension-bearing polypeptide chains (cf. Section III, 11), since for this reaction $-\Delta H$ is numerically greater than $-\Delta F$ (refs. 30–32) (see Section IV, 6). Stretching an activated muscle should, therefore, not lead to a resynthesis of ATP and such a muscle could readily absorb work with little energy output[24].

(17) This theory also makes possible a tentative unification of the basic mechanism of contractions occurring in skeletal and cardiac muscle with those in smooth muscle, vorticella, bacteriophage tails and perhaps flagellæ, cilia and sperm tails. There is good evidence for the operation of a sliding-filament mechanism in smooth muscles[21,33]. Fig. 7 shows a possible mechanism by which a particular smooth muscle could both be stretched by large amounts and contract by large amounts with formation of contraction bands (cf. ref. 34). This mechanism would also account for the helical arrangement of fibres in many smooth muscles. The existence of long thick filaments in many types of smooth muscle would account for the high tensions found because there will be large numbers of cross-links. For example, in the translucent adductor of the oyster, there are twelve thin filaments around each thick filament[21]. Hoffman-Berling[35] concluded that the contraction of vorticella stalks is due to the blocking of the excess negative charge on the contractile protein by calcium ions and that this is reversed in the relaxation phase by means of ATP. This is clearly very similar to the postulated contraction-relaxation cycle of part of the *H*-meromyosin presented here. Wahl and Kozloff[36] found that one nucleoside triphosphate and one calcium ion are associated with each sub-unit of the contractile part of the tail of T-even *E. coli* bacteriophages. The presence of the nucleotides seems to maintain the relaxed state, and contraction occurs only in the absence of ATP and is independent of ATP hydrolysis. This is similar to the rigor contraction of muscle. Several other types of contraction have been discussed by Weber[28].

(IV) Quantitative Conclusions

This theory can be used to make approximate quantitative estimations of: (1) the amount of calcium needed for maximum tension development; (2) the length of the latent period; (3) the heat of activation; (4) the force developed and the work done per ATP at the cross-bridges during muscle contraction; (5) the energetics of the individual extension–contraction steps; and (6) the heat changes during shortening and stretching of active muscle.

(1) According to H. E. Huxley[1] each half of each thick filament of rabbit psoas muscle has 18 sets of 6 helically arranged side pieces (Fig. 1). There are about $2{\cdot}5 \times 10^{14}$ thick filaments and $5{\cdot}4 \times 10^{16}$ cross-bridges per 1 ml. Since 1 g molecular weight contains 6×10^{23} molecules, the amount of calcium required to link with the ATP on each *H*-meromyosin is 0·09 μmoles/g. Heilbrunn and Wiercinski[37] obtained maximum contraction of small pieces of frog striated muscle fibres (adductor magnus of *Rana pipiens*) by intracellular injection of one-tenth volume of 1·25 mM calcium chloride, that is, 0·125 μmoles/g of muscle. Just discernible effects were obtained with 0·02 μmoles/g. Since some calcium is probably bound on other structures, this is a remarkably good agreement. Injection of higher concentrations caused local contraction and coagulation[37,38].

(2) This theory requires that, on activation, the calcium is removed from its binding sites and moves to the cross-bridges from the sarcoplasmic reticulum in twitch fibres or from the surface and invaginations of the sarcolemma in striated tonus fibres and in smooth muscle during the latent period, which is about 10 msec in frog sartorius at 0° C. Peachey (private communication) has shown that the diffusion distances involved in many varieties of fast muscle are of the order of 1 μ. Thus the diffusion time for calcium fits nicely in this period, even after allowing for a tortuous pathway around the filaments for several cycles of formation and breakage of bonds with cytoplasmic ATP and inorganic phosphate[39] and for the estimated time for the extended flexible ATP-bearing polypeptide chain to snake around into the exact position for link-formation. The intermediate chemical reactions would have much higher temperature coefficients than simple diffusion and this may account for the high temperature coefficient of the latent period[1]. The rediscovery of the sarcoplasmic reticulum has thus solved the apparent mystery of the problem of excitation–contraction coupling[40].

(3) The heat of activation is identified here as the heat associated with the removal of calcium from the sarcoplasmic reticulum. This amount of heat is not known at present, but an order of magnitude calculation may be made from the heat of dissociation of calcium phosphate which is +5 kcal/mole (ref. 14). Since some extra energy must be provided, probably from the influx of sodium ions on excitation, in order to free this tightly bound calcium, this heat is probably between 5 and 10 kcal/mole. If the total heat for this step were 10 kcal/mole the heat of activation would be 0·9 mcal/g muscle in agreement with the 1–1·5 mcal/g (ref. 41) found by thermal measurements.

(4) Recent results from these laboratories[6] show that under normal physiological conditions 0·64 μmole ATP/g muscle is used when 120 g-cm of external work is done in a single contraction of frog rectus abdominis muscle. Under these conditions the actual free energy of ATP hydrolysis to ADP is about 10 kcal/mole (ref. 42), but is less when the ratio of products to reactants increases[6]. Thus the normal efficiency of energy transduction is about 44 per cent (that is, this step is nearly thermally neutral[30]) and, of the 7×10^{-13} erg from each molecule of ATP, about 3×10^{-13} erg is used for work. H. E. Huxley[1] has found that the number of cross-bridges in each tension-bearing unit of half a sarcomere length in a 1 cm² cross-section of rabbit psoas muscle is about $6{\cdot}5 \times 10^{12}$. Since the maximum tension developed by skeletal muscle is approximately 2 kg/cm², and this would be when all the cross-bridges are linked to actin, the force per link is on average 3×10^{-7} dyne. Since the work is 3×10^{-13} erg the distance moved is about 100 Å per ATP. A similar conclusion has been reached by both H. E. Huxley[1] and A. F. Huxley[4], but their calculations were based on estimates from measurements of heat changes and work done during contraction, and are thus thermodynamically objectionable since entropy changes were neglected and, in any event, were unknown. However, if, on average, only half the cross-bridges could link to actin at maximum tension, the movement per ATP would be about 50 Å, that is, about the length of a *G*-actin sub-unit of a F-actin filament, and the force would be twice as great per link for the same work per ATP molecule. In any event, it seems possible that the actin may spin as it slides in, and thus maintain optimal steric conditions for cross-link formation.

(5) It is clear that when a muscle moves quickly there is less chance of any particular cross-link being formed in time since this depends on a precise hit of the actin site, the calcium and the bound ATP. If a muscle is stretched until the actin filaments just overlap the myosin filaments, and then stimulated and made to do maximal work during contraction until the ends of the actin filaments reach the innermost cross-bridge of the myosin filaments, this should require a movement of 18 × 400 Å (Fig. 1), that is, 7200 Å per half sarcomere. There would be an average of 36 contraction-relaxation cycles per cross-bridge for a movement equal to 63 per cent of the rest length of the muscle, which would cause a breakdown of $36 \times 0{\cdot}09 = 3{\cdot}2$ μmoles ATP/g. This can be tested experimentally. In the frog muscles[6] (rectus abdominis) which did 120 g-cm of work and contracted by 41 per cent for a breakdown of 0·64 μmole ATP/g, the average number of contraction-relaxation cycles was $0{\cdot}64/0{\cdot}09 = 7$ per cross-bridge. Thus, most of the cross-bridges did not form links continuously during all the total rapid movement of about 4700 Å per half sarcomere.

Assuming that for maximum velocity of shortening in unloaded vertebrate muscles only one link is needed on the average between each actin filament and a myosin filament then such a muscle, shortening from rest length by even 50 per cent would break down only about 0·1 μmoles ATP/g, but at a very rapid rate.

This accounts for why it has been found that the amount of ATP, measured as phosphorylcreatine, cleaved during single contractions of unloaded rectus abdominis muscle, is so low as to be not significantly different from zero with the present experimental errors and biological variability[6]. This could also explain similar results on the lack of increase of creatine in contraction of lightly loaded turtle muscles found by Mommaerts *et al.*[43].

It follows that there is no major 'shortening' ATP breakdown[6,23], independent of work, corresponding to Hill's 'shortening heat'[27].

This theory is based on the assumption that the work done by the repulsion of the (assumed) fixed negative charge on the *H*-meromyosin and the negative charge on the terminal phosphate of the bound ATP comes from the distortion of the ATP and exists as potential energy in the extended polypeptide chains. On neutralization of this negative charge of ATP by calcium ions, the structure contracts to an α-helix, develops tension, and delivers up as work the excess of the free energy of hydrogen-bond (and hydrophobic-bond) formation over that associated with the loss of configurational entropy of the structure. The potential energy gained by the structure can be calculated roughly from the data given by Schwarzenbach[44]. His results show that a dielectric constant of about 12 is reasonable for a region that would be full of organic material, since the repulsion acts through the extended polypeptide chain and its associated peripheral organic residues. Thus the system would carry the electric force like an insulated cable. It follows from his Fig. 1 that movements of the charges from a distance of 6 Å–110° Å would involve just 3×10^{-13} erg per pair of charges. Most of this energy change would occur in the first few ångströms and would be needed to start the splitting of all the hydrogen bonds to open the α-helix. Thus the amount of energy needed for the active extension of the cross-bridge polypeptide is in very satisfactory agreement with that available and is, of course, delivered to the system when the bound ADP is phosphorylated by cytoplasmic ATP (Fig. 4) near to the fixed negative charge on the *H*-meromyosin. Thus 40 per cent of the energy delivered would be used to extend the polypeptide chain. Clearly, the maximum amount of work which could be recovered from the system during the subsequent contraction (Fig. 4) is the free energy put into it during the active extension. However, the actual work would be less if the reformation of the α-helix delivered less energy during contraction. It is not possible to calculate or measure this precisely because the exact structural details are not yet known. However, if the situation is similar to that in Fig. 4, a reasonable conclusion can be reached.

Investigations of the helix-coil transformation of several synthetic polypeptides have shown the importance of hydrogen-bond formation, configurational entropy of extension, electrostatic interactions, hydrophobic-bond formation, and "end effects"[31]. Thus polyglutamic acid only exists as an α-helix at a low *p*H value. It becomes a random coil at high *p*H values because of repulsion between the ionized carboxyl groups which will tend to extend small lengths of the chain into the fully extended β configuration. α-Helices have a pitch of about 5·4 Å and contain 3·6 residues per turn, so if the terminal portion of the mobile *H*-meromyosin polypeptide contains 50 amino-acid residues it would have nearly 14 turns in the α-helix configuration and be 75 Å long (Fig. 6). In the randomly coiling form the electrostatic repulsion for such a small polypeptide would favour the existence of an extended form of the chain for part of the time. It would be a helix of 3·0 residues per turn with the amino-acid *R* groups extending out at 120° from each other. The backbone would be 3·6 Å per residue and, since its total length would then be 180 Å, it would have extended by 105 Å. The α-helical form would fit neatly into the observed height of the side pieces as seen in electron-micrographs of muscle.

The helix-coil transformation of polyglutamic acid of molecular weight 22,000 occurs in the *p*H range of 4·6–

5·2 at 20° C in 0·2 M sodium chloride and over a change in the degree of ionization of 0·36–0·64. This shows that the stabilization of the α-helix by the 3·6 hydrogen bonds per turn counterbalances the loss of configurational entropy on forming the rigid structure. This does not mean that for a 50-residue *H*-meromyosin α-helix to be unstable more than 18 ionized carboxyls need to be present on the periphery of the protein cylinder, small helices being inherently unstable due to 'end-effects' since four hydrogen bonds cannot be formed. Small helices probably have critical sizes of the order of 15–20 residues, neglecting residue interaction, but even so it is likely that several glutamic or aspartic acid residues would be needed to loosen this postulated structure to the point where it is almost unstable and then an extra negative charge would cause the unzipping of all the oriented hydrogen bonds with a consequent gain in configurational entropy[31]. Since the α-helix could be made more or less stable by appropriate changes in the *R*-groups, it follows that for this tension-bearing peptide chain, virtually all the work done by the repulsion of the fixed negative charge and that on the terminal phosphate of the ATP could be used effectively. On the neutralization of this negative charge on the ATP the system would spontaneously contract smoothly, assisted by Brownian vibrations, and gain energy for additional work by increments as each of the 46 hydrogen bonds was formed by the 50 residues. Most of the net free energy of the change to intramolecular hydrogen-bond formation (approx. 1,000 cal/mole)[32] would be balanced by charge interaction of the *R*-groups and by the loss of configurational entropy. The rest would do the work of muscle contraction, that is, 3×10^{-13} erg/cross-link, and would develop an average of 3×10^{-7} dyne during a 100 Å contraction of each mobile polypeptide. This is a simplified statement since there will be changes in the complex interactions between the amino-acid *R*-groups.

It is interesting that the work done by the ATP in extending the polypeptide, and the free energy released by the formation of hydrogen bonds on contraction are equal. However, the stretching force from the charged ATP varies inversely as the square of the distance whereas the contractile force will be the summation of many equal pulses as the peptide coils to form the α-helix. Thus the fully extended chain will be unstable and only a small percentage of the time will be spent in this configuration. In any event, as the extended chain snakes by thermal motion the chain will bend and allow some of the aqueous phase of the cytoplasm to get between the bound ATP and the fixed negative charge so the effective dielectric constant will increase, the repulsion drop and the chain start to contract to a helix. However, as soon as it had pulled itself back sufficiently it would have to straighten out again so the repulsion would increase again and return the chain to its more extended form (Fig. 6). Thus this polypeptide of the *H*-meromyosin with the bound ATP on its end would spend much of its time in a partly random coil configuration but, because of the charge repulsion and Brownian motion, would exist for part of the time as a fully extended chain. It would continuously sweep out the available volume and, in the presence of calcium, would be able to make a link with any *F*-actin ADP site within reach.

It is necessary to show that α-helices could bear the tension developed in muscle. Enomoto and Krimm[45] recorded values and calculated that the elastic modulus in several natural and uncharged synthetic polypeptides is of the order of 5×10^{10} dynes/cm² for α-helices and 2×10^{11} dynes/cm² for extended chains. This elastic modulus of 5×10^{10} dynes/cm² is based on 10^{14} helices/cm² with an overall helical diameter of about 10 Å. The peculiar structure of muscle with its effective $6{\cdot}5 \times 10^{12}$ sites/cm² means that there are about one-fifteenth as many helical cross-bridge polypeptides available as in normal fibrous proteins. Thus the maximum tension in muscle (approximately 2×10^6 dynes/cm²) would extend the cross-bridge α-helices by only about 0·1 per cent if they were similar to those studied[45] (cf. Section III, 17, for smooth muscle). This shows that the proposed tension-bearing structure would be able to bear the actual tension. It may even need to be made less stable by electrostatic repulsion of, for example, glutamic or aspartic acid residues (which occur in *H*-meromyosin[46]) so that the extra negative charge from the bound ATP could extend the structure and break the α-helix. Since the α-helix is well able to bear the tension, the extended chain, which has a higher elastic modulus, must also be able to do this. The strong electrostatic attractions operating over only a few Å which chelate the calcium to the *H*-meromyosin ATP and the *F*-actin ADP and which bind the ATP to the myosin are also clearly able to bear the tension of muscle[44,47].

(6) The frog muscles[6] (rectus abdominis) (Section IV, 5), which did a full smooth tetanic contraction, weighed 180 mg and contracted by 2·1 cm. The isometric tension, P_0, was 65 g-wt., so Hill's[17] constant a was 16 g-wt. and the experimental shortening heat[17] would be 34 g-cm, that is, 190 g-cm/g or 4·4 mcal/g (cf. Hill[41]). This contraction would cause all the cross-bridges to form α-helices during the shortening (Section IV, 5).

The initial formation of the calcium chelate link between the *H*-meromyosin and the actin (Fig. 4) probably causes a heat uptake of the order of 10,000 cal/mole (cf. Section IV, 3, and ref. 14). This, together with the 46 hydrogen bonds formed per bridge (Section IV, 5) and a heat output of 1,500 cal/mole of hydrogen bonds[31,32], gives a calculated heat of shortening of 5·3 mcal/g which would be reduced proportionately if the polypeptide were already somewhat contracted when the chelate link was formed. This is a very satisfactory agreement for such a rough calculation. The theory predicts that shortening heat should be less during very lightly loaded, and hence very rapid, contractions when many cross-bridges will not interact even once.

An activated muscle will have a similar but negative heat of extension from the reverse of these reactions (cf. Section III, 11), since the work (free energy) needed to stretch the partially contracted tension-bearing polypeptide cross-bridges (4,000 cal/mole bridges) is only about one-seventeenth the associated heat change (see Sections III, 16; IV, 5. 6, refs. 30–32). The stretch will eventually pull apart the calcium chelate bonds so the tension should, and does[1], rise above the maximum isometric tension. The extended chain with its bound calcium will start to contract freely since the negative charge on the bound ATP remains neutralized, but it could form another link with actin as it shortens and would again resist the external stretching force (Figs. 1–6). Most important, the cyclic breakdown of ATP (coupled to phosphorylcreatine) will not have occurred and this could account for the observation that Hill's constant a for the negative heat of lengthening[48] can be several times that for the heat of shortening.

It is thus expected that "mechanical work applied to a contracting muscle by stretching it may reduce the net energy liberated by the muscle itself, either to nothing, or to an amount much less than in a similar contraction without stretch"[48].

This theory proposes that the activation of muscle releases bound calcium from the sarcolemma and the sarcoplasmic reticulum. This calcium diffuses and forms chelate links between bound ATP at the end of an asymmetrically extended rapidly snaking polypeptide of the cross-bridges of the *H*-meromyosins of the myosin filaments and the bound ADP of the *F*-actin filaments. The calcium neutralizes the electric charge on the bound ATP of the polypeptide which spontaneously contracts to an α-helix by the energy of hydrogen-bond and hydrophobic-bond formation. This contraction drags the actin filament along the myosin filament. This brings the ATP into

the range of action of the *H*-meromyosin ATPase, which cleaves off the terminal phosphate and breaks the link. On rephosphorylation of the ADP the helix is pulled out to a largely extended chain by the repulsion of the negative charge on the ATP and a fixed charge on the *H*-meromyosin. This cycle is repeated during the active state, which ends when the calcium is pumped back into the sarcoplasmic reticulum and sarcolemma. It seems that, in principle, this type of mechanism, which includes both sliding and folding, can account for many qualitative and quantitative observations on contraction of skeletal, cardiac and smooth muscles and of several other biological systems. It leads to predictions which can be tested experimentally.

I thank Drs. Helen C. Davies, R. J. Rutman and D. R. Wilkie and Profs. A. V. Hill, P. George and J. M. Marshall for commenting on early drafts of the manuscript.

A NEW STAPHYLOCOCCAL ANTIGEN

Its Preparation and Immunizing Activity against Experimental Infections

IN the course of investigations in these laboratories on protective antibody against the *Smith* strain of *Staphylococcus aureus* in human γ-globulin[1,2] and human serum[3], it appeared to one of us (M. W. F.) that *Staphylococci* of this type may be immunologically unique. We therefore investigated this and other staphylococcal varieties with respect to their ability to induce resistance to challenge infections. After testing and evaluating the mouse-protective immunogenicity of vaccines made from numerous isolates of *S. aureus*, we discovered that only certain infrequently occurring strains had this property. We further ascertained that such strains were generally of the *Smith* type and that by treating cultures of these strains in the manner to be described here, a distinctive highly potent immunizing polysaccharide could be produced. This polysaccharide, which we have designated 'SPA' (staphylococcal polysaccharide antigen), is described in the following communication with respect to its physical and chemical characteristics. This communication deals with the preparation of SPA from cells and presents some of its salient biological properties.

SPA is prepared from cells of an especially useful strain of *S. aureus*, designated by us as '05068'. Like the *Smith* strain, '05068' is highly virulent for mice, it produces diffuse colonies in serum-soft agar[4], and it is not lysed by standard phages. Trypticase soy broth (Baltimore Biological Laboratories) was used for relatively small-scale cultivation of this organism under static or shake flask conditions.

Two procedures were developed to produce SPA. One method consisted of mechanically blending a washed cell mass with 85 per cent phenol at 50°–55° C for 4–6 min.

The resultant phenol-insoluble precipitate was washed with 85 per cent phenol, suspended in water and dialysed to remove phenol. The water-insoluble portion, which contained most of the immunizing activity, was treated with 0·1 N acetic acid to *p*H 3·2 and autoclaved at 121° C for 15 min. This process resulted in a water-soluble preparation of high SPA content.

Another and simpler process consisted of directly treating the washed cell mass with 0·1 N acetic acid at 100° C for 5–20 min. This method also provided a water-soluble portion rich in SPA, with the cellular debris being essentially inactive. Procedures for the further purification of SPA as well as for its colorimetric assay will be reported in detail elsewhere.

The high degree of immunizing activity of SPA for mice is illustrated by the results in Table 1. In this typical test, groups of female *CF*-1 albino mice, 18–22 g, were injected subcutaneously with a single dose of various amounts of SPA. Seven days later these and untreated mice were acutely challenged with 10^4 LD_{50} of '05068' staphylococci given intraperitoneally in 5 per cent hog gastric mucin. The survival percentages, based on observations made 5 days later from initial groups of 20 mice, indicate a 50 per cent protective dose (PD_{50}) of about 0·004 μg/mouse.

'Immune paralysis', similar to that noted for pneumococcal polysaccharide[5], is also revealed by the results in Table 1. In this example, the 50 per cent 'paralysing dose' of SPA is estimated as 0·12 μg/mouse, or 30 times greater than the PD_{50}.

SPA will also immunize mice against challenge by other strains of *S. aureus*. Unequivocal resistance to challenge was found in experiments, like that previously described involving the following strains: *Smith, H and D, Castellani, 1-AV, S193N4, MCG-138, K6, K93, K93M, Adams* and *Welwood*. In addition to an apparent immunological homogeneity, these strains have the common feature of being unusually virulent for mice. A low degree of elevated resistance was provided by SPA to mice challenged with various isolates of phage type 80/81. However, the necessity for use of very heavy challenge doses of 80/81 staphylococci may have served to occlude or diminish immune effects. SPA did not alter the susceptibility of mice to challenge by any of the following bacteria: *Diplococcus pneumoniae, Streptococcus pyogenes, Strept. salivarius, Klebsiella pneumoniae, Escherichia coli, Proteus mirabilis* and *Pseudomonas aeruginosa*.

Challenge immunity was detectable in mice during 36–48 h after an injection of SPA and such resistance was still demonstrable 70 days later. SPA appeared to be of equivalent efficacy whether given subcutaneously, intradermally, intramuscularly or intravenously. However, multiple or divided doses of SPA proved to be less immunogenic for mice than a single dose.

The direct relationship between protective antibody and challenge resistance in mice is indicated by the results shown in Table 2. In this experiment groups of 40 mice were injected with various doses of SPA. Seven days later, half the mice were challenged with 10^3 LD_{50} of the *S193N4* strain, given intraperitoneally in mucin. The remaining 20 mice at each SPA dose-level were exsanguinated, their serum pooled, and a passive test run on each.

Further details of extensive biological studies on SPA will be reported at a later date. These other experiences have revealed that SPA will stimulate the appearance of protective serum antibody in mice, dogs, and human beings, but will not do so in guinea pigs, rabbits and monkeys. The ability of SPA to prevent or modify natural infections of animals and man is at present being investigated and the results of these studies should serve to resolve the disagreement[6,7] on the relevance of *Smith* strain immunology to clinical disease.

Table 1. Mouse Immunizing Activity of SPA

SPA dose (μg/mouse)	Per cent protected
None (untreated)	0
0·002	5
0·006	50
0·02	60
0·06	80
0·2	20
0·6	0

Table 2. Correlation of Active and Passive Immunity in Mice

SPA dose (μg/mouse)	Per cent protected vs. challenge	Serum titre*
None (untreated)	0	<2
0·001	20	20
0·01	75	40
0·1	100	180
1·0	100	350
10·0	65	65
100·0	5	<2

* Reciprocal of 50 per cent protective dilution of serum[3].

2-Amino-2-deoxy-D-glucuronic Acid, the Main Constituent of SPA (Staphylococcal Polysaccharide Antigen)

In the preceding communication, Fisher *et al.* have reported on the preparation and biological evaluation of a pure polysaccharide antigen from the cells of a staphylococcal strain of unique immunogenicity. This product, designated SPA, was shown to possess active immunizing properties in mice, dogs and man. We wish to report some of the physical and chemical properties of SPA together with degradation studies leading to the elucidation of its main structural features. The polysaccharide consists of 2-acetamido-2-deoxy-D-glucuronic acid and 2-[(*N*-acetylalanyl)amino]-2-deoxy-D-glucuronic acid residues linked by 1 → 4 type linkage (probably β). Active antigenic preparations also contained about 7–8 per cent *O*-acetyl groups as determined by the quantitative hydroxamate test[1].

Acidic hydrolysis techniques were used by Fisher *et al.* to produce SPA from whole bacterial cells. This was most conveniently carried out by heating the cells with 0·1 N acetic acid at 100° for brief periods (5–20 min). We also have produced SPA by stirring the cells with 5 per cent trichloroacetic acid at room temperature for 20–24 h. The crude SPA was then purified by a combination of methods, including carbon chromatography and alcohol fractionation. Pure SPA was found to be an acidic polysaccharide free of nucleic acid, protein and lipid.

SPA could be detected and its electrophoretic mobility studied on both glass fibre[2] and paper strips. It appeared as a pink spot when sprayed with the *p*-anisidine–sulphuric acid in *n*-butanol reagent on glass fibre strips. Detection on paper strips was accomplished by utilizing the amide spray of Rydon and Smith[3]. At *p*H values greater than 4, SPA migrated as an anion. In the Tiselius apparatus, SPA migrated as a homogeneous entity with an observed mobility constant of $5{\cdot}87 \times 10^{-5}$ cm^2 sec^{-1} V^{-1} in *p*H 6·0 phosphate buffer. Homogeneity was also apparent from ultracentrifugal studies whereby a single symmetrical peak, $S^{w}_{20} = 1{\cdot}7$ Svedberg units, was obtained in 0·1 M phosphate buffer at *p*H 7·0 for material prepared by extraction with trichloroacetic acid.

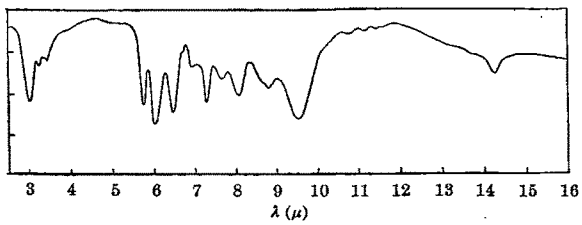

Fig. 1. Infra-red spectrum of SPA in compressed potassium bromide

Purified SPA is a white amorphous solid which in its salt form is freely soluble in water and is not readily precipitated from dilute salt solutions with alcohol. The polysaccharide shows no absorption maxima in the ultra-violet range. The infra-red spectrum of the free acid form samples of SPA prepared from various source materials is shown in Fig. 1. Elemental analysis of six different showed the following average values: C, 44·7; H, 6·30; N, 8·20; P, < 0·06, ash 0·38. Aqueous solutions were strongly lævorotatory ($[\alpha]_D^{23} - 91°$, *C* 1, in 0·1 M phosphate buffer at *p*H 7·0). The polysaccharide had an acidic dissociation constant (pK_a) of 3·3 in water. The failure to be adsorbed on sulphonic acid exchange resins demonstrated the absence of basic groups in SPA. Tests for uronic and sialic acids and with the Molisch or anthrone reagents were negative. The intact polysaccharide gave a negligible reducing value and failed to reduce periodate solutions.

Acid hydrolysis (4 N hydrochloric acid at 100°) revealed the presence of a neutral amino-acid, an amphoteric amino-sugar, and a considerable amount of humin. No other known sugar component was detected in hydrolysis studies under a variety of conditions. The amino-sugar moved by endosmosis during electrophoresis at *p*H 5 and gave positive tests with ninhydrin, Elson-Morgan[4] and silver nitrate[5] reagents. On paper chromatograms the amino-sugar had an identical mobility to that reported for synthetic 2-amino-2-deoxy-D-glucuronic acid[6]. Since efforts to crystallize this substance failed, the parent polysaccharide was converted to the methyl ester (0·07 N methanolic hydrogen chloride for 24 h or diazomethane in methanol–water). The ester was reduced with lithium borohydride in formamide–tetrahydrofuran solution until the 5·78-μ ester band had practically disappeared from the infra-red spectrum of the product. Acid hydrolysis of the reduced polysaccharide resulted in the formation of much less humin and a new amino-sugar corresponding to glucosamine by paper chromatography. Crystalline D-glucosamine hydrochloride was afterwards isolated from such hydrolysates and characterized by optical rotation and X-ray diffraction pattern data. The precursor of D-glucosamine and the only detectable carbohydrate present in SPA is therefore 2-amino-2-deoxy-D-glucuronic acid. The neutral amino-acid present in SPA was found to be L-alanine and was characterized by optical rotation, infra-red spectra and microanalysis.

Aminohexuronic acids have been previously isolated as decomposition products of bacterial cell walls. Heyns *et al.*[7] found 2-amino-2-deoxy-D-galacturonic acid to be the main constituent of the *Vi* antigen, while Perkins[8] reported the presence of 2-amino-2-deoxy-D-mannuronic acid in hydrolysates of cell walls of *Micrococcus lysodeikticus*. Perkins[8] also suggested the presence of 2-amino-2-deoxy-D-glucuronic acid in an antigen described by Morse[9] which is different from but possibly related to SPA.

Methylation and hydrolysis examinations of the parent and reduced polysaccharides confirmed the glycosidic linkage as 1 → 4. Thus the reduced polysaccharide was methylated (14·53 per cent OCH_3) by a modification of a method described by Stacey and Wooley[10] and on hydrolysis (2 N hydrochloric acid, 3 h) afforded a major methylated monosaccharide which was isolated by preparative paper chromatography. Selective *N*-acetylation then afforded crystalline 2-acetamido-2-deoxy-3,6-di-*O*-methyl-D-glucopyranose, identical with an authentic sample. The only other detectable methylated monosaccharide was formed in small amount and corresponded to 2-amino-2-deoxy-6-*O*-methyl-D-glucopyranose.

Alternatively the parent polysaccharide was methylated (9·0 per cent OCH_3) by a modification of the Kuhn procedure[11] and the product was then esterified and reduced with lithium borohydride. Acid hydrolysis followed by separation and N-acetylation of the single methylated monosaccharide product afforded crystalline 2-acetamido-2-deoxy-3-*O*-methyl-D-glucopyranose, identical in all respects to an authentic sample.

The identity of the repeating monosaccharide units in SPA was established indirectly by mild acid hydrolysis (1 N acetic acid at 108°, 16 h in a sealed system) of the reduced polysaccharide. Under these conditions, the totally dialysable products consisted predominantly of an *N*-acyl-D-glucosamine derivative. Small amounts of alanine, D-glucosamine and a sugar with identical electrophoretic and paper chromatographic mobility as 2-(alanylamino)-2-deoxy-D-glucose were formed. Purification and separation of the *N*-acyl-D-glucosamine component by chromatographic techniques afforded a colourless solid which, on acid hydrolysis, revealed alanine and glucosamine only. Since synthetic mixtures of 2-acetamido-2-deoxy-D-glucopyranose and 2-[(N-acetylalanyl) amino]-2-deoxy-D-glucopyranose could not be separated on paper chromatograms with a variety of solvent systems, optimum hydrolysis conditions for the liberation of alanine and glucosamine from above mixtures were established. Quantitative analysis of the *N*-acyl-D-glucosamine product showed an alanine–glucosamine ratio of 1 : 2. A solution of the *N*-acyl-D-glucosamine component in a water–methanol–acetone mixture deposited crystals of 2-acetamido-2-deoxy-D-glucopyranose. The mother liquors consisted predominantly of 2-[(*N*-acetylalanyl) amino]-2-deoxy-D-glucopyranose. The repeating units of SPA therefore appear to be equimolar amounts of 2-acetamido-2-deoxy-D-glucuronic acid and 2-[(N-acetylalanyl)amino]-2-deoxy-D-glucuronic acid.

Mild acid hydrolysis on the parent polysaccharide (SPA) as described here also produced a completely dialysable product. The main components were isolated by chromatographic techniques and consisted of a mixture of *N*-acyl-D-glucosaminuronic acid and its lactone as evidenced by electrophoresis studies at *p*H 5 and colorations with the Morgan–Elson[5] and hydroxylamine sprays[12]. Solutions of the lactone remained homogeneous on chromatography, while the *N*-acylated component equilibrated partially to the lactone.

Staphyloccal polysaccharide antigen, therefore, differs chemically from all other staphylococcal degradation products previously described in that it is composed of two main components, L-alanine and 2-amino-2-deoxy-D-glucuronic acid with *O*- and *N*-substitution by acetyl.

We thank the personnel of the Microbiology Research Department at Parke-Davis for supplying source materials and biological testing. We also thank Dr. H. M. Crooks for valuable discussions and advice.

INFLUENCE OF TEMPERATURE AND AGEING ON ETHYLENE PRODUCTION BY A SUB-CELLULAR FRACTION FROM TOMATOES

By Prof. MARY SPENCER and M. MEHERIUK
Departments of Plant Science and Biochemistry, University of Alberta, Edmonton, Canada

THE production of ethylene by sub-cellular particles is affected by many conditions, including disintegration of the particles, and reaction mixture constituents[1–3]. In an attempt to resolve to some extent the evident complexity of factors governing the evolution of ethylene by sub-cellular fractions, studies were made of the effects of temperature and ageing on production of the gas. Preparation of the fraction separating at 35,000*g* from tomato homogenates, and the method of analysis for ethylene, have been described previously[4,5]. Confirmatory analyses were made periodically by direct sampling of the gas mixture in the reaction vessel without absorption in mercuric perchlorate, and by disappearance of the ethylene peak from the gas chromatogram when the sample was shaken with bromine water. Comparisons were made only among fractions from the same particulate preparation, since considerable variation in ethylene-producing activity may be expected with particles from different runs[4].

Meigh[2] reported that boiling or evacuating a mitochondrial suspension from tomatoes before sonication had little effect on hydrocarbon production whereas these treatments after sonication resulted in marked decreases. (He did not specify whether comparisons were made among particles from the same preparation.) In drawing conclusions about the ethylene-producing activities of boiled and unboiled particles, distinction must be made between pre-formed ethylene, liberated on disruption of the particles, and that actually formed after boiling. We found that when the particulate suspension was evacuated and then aerated to remove much of the ethylene initially present, boiled particles on sonication gave two-fifths the amount of ethylene produced by unboiled particles, identically evacuated, aerated and sonicated. Moreover, there was no further ethylene liberated by the boiled fraction on ageing for 20 h. The presence of active, unboiled particles was necessary for this evolution.

When the particles were sonicated before boiling, and the ethylene liberated during these processes was removed by aeration and evacuation, little or no ethylene was detectable. However, if collection of ethylene was made during boiling of the sonicated particles, large amounts of gas were obtained (Table 1, run 8). This high initial outburst might be suggestive of increased enzyme activity for the short time prior to denaturation of enzymes, or of thermal activation of strictly chemical or physical reactions. In all our experiments no ethylene was evolved by boiled particles after the first hour of collection, whereas unboiled particles continued to produce the gas. In our earlier work[1,4] also, we showed a continued production by unboiled particles during a 4–20-h reaction period.

Evacuation of the sonicated, unboiled particulate suspension and maintenance in a closed system[2] would be expected to result in lower ethylene production for a 2-h collection period. This might, for example, be due to removal of ethylene immediately evolved on disruption of the particles.

Further insight into the nature of the processes involved in ethylene production was sought from experiments in which the effects of intermediate temperatures on ethylene evolution were studied. Representative results are shown in Table 1. For these runs the sub-cellular particles were sonicated in the complete substrate and the reaction vessels were connected to the collection system before immersion in water baths of the appropriate temperature.

Table 1. Effects of Temperature on Ethylene Evolution by Sonicated Sub-cellular Particles from Tomatoes

Particles were suspended in the complete reaction mixture: 0·5 M sucrose, 0·125 M KH_2PO_4, 10^{-3} M $MgSO_4$, 10^{-3} M $MnSO_4$, 0·05 M L-malic acid, adjusted to *p*H 7·0 with NaOH; ATP (10^{-3} M) was added after sonication.
N = not detectable: T = trace.

For each run, half the reaction mixture was kept at 25° C, and the other half at a different temperature.

When ethylene evolution at 25° C was used as a basis for comparison, it was observed that the initial (0–2 h) gas production was less at 0° C and greater at 100° C, while at intermediate temperatures it did not differ greatly from that at 25°. Evolution for the subsequent period was greater at 0° and 15° than at 25° C, about the same at 20° and more at 30° C. At 40° and 50° it decreased, and at 100° there was no ethylene production during this period. Total evolution over the entire 20-h period relative to the 25° controls was highest at 15° and 30° (Table 1).

These results suggest that the initial production may not be entirely due to enzymatically controlled reactions, although, as mentioned previously, the high initial evolution at 100° could be the result of increased enzyme activity for a short interval before denaturation commences. Consideration of the ethylene yield for the 2–20-h period, as well as the total ethylene yield, reveals a common maximum in close agreement with the optimum temperature of 33° reported for ethylene production by tomatoes *in vivo*[6,7]. However, the second maximum at 15° C, and the variation in ethylene production between two halves of one particulate preparation on ageing[1], suggest the existence of some further controlling reactions, either enzymatic or non-enzymatic, in the sub-cellular system.

Experiments with intact rather than sonicated particles showed that, boiled or unboiled, they produced little ethylene. (Ethylene collections were made during the entire boiling period.) These results are in agreement with our previous experiments with unboiled particles, from which we showed that production of ethylene was related to disintegration of the structure of the particles[4]. When unboiled particles were aged overnight, then sonicated, a very large amount of ethylene was produced. This did not occur with boiled particles, once again illustrating the difference in behaviour between boiled and unboiled suspensions. The fact that boiled intact particles fail to produce ethylene or liberate significant amounts of the gas on sonication after ageing could be due to inactivation of the enzymes involved in the production of the volatile or to destruction of the components necessary for a non-enzymatic evolution of the gas.

Additional experiments were conducted to investigate the nature of the very large increase in ethylene production which occurred when particles were aged before soni-

In run 1, parts *A* and *B*, and run 2, particles were suspended in sucrose-phosphate: 0·5 M sucrose, 0·125 M KH_2PO_4, *p*H 7; in parts *C* and *D* of run 1, the complete reaction mixture given in Table 1 was used. All runs were at room temperature.

cation. The effect of reaction mixture components was measured by ageing the particles in a complete reaction mixture and comparing their ethylene-producing ability with that of particles aged in sucrose–phosphate buffer. Also, the effect of re-sonication after ageing, of previously sonicated preparations, was tested. For these experiments the sub-cellular particles obtained from 1 kg of tomatoes were halved, suspended in either sucrose–phosphate buffer or the complete reaction mixture, and each suspension was halved again for further treatment. Equal and homogeneous division of particles before suspension in any medium was, of course, impossible. Comparison of results expressed on a nitrogen basis may not be entirely valid since there is no evidence for a close relationship between total nitrogen content and the factors responsible for ethylene production. Despite these limitations of interpretation, it is evident from the results in Table 2 that a large increase in ethylene production occurred when particles were aged in sucrose–phosphate buffer, as well as when they were aged in the complete reaction mixture. Furthermore, initial sonication did not markedly affect the ethylene production on ageing and re-sonication of particles suspended in sucrose–phosphate (run 1, parts *A* and *B*). Larger total ethylene production by particles suspended in sucrose–phosphate was obtained with initial sonication.

When the particles were suspended in the complete reaction mixture, initial sonication resulted in reduced ethylene production after ageing and re-sonication (run 1, parts *C* and *D*). Considerable ethylene was evolved during ageing of the sonicated particles, and total production was either about the same, or greater than that of particles aged before any sonic treatment. (Re-sonication after short ageing periods did not result in production of a large amount of ethylene (Table 2, run 2). Similar results were obtained when the particles were suspended in the complete reaction mixture.)

Thus both initially intact and sonicated particles generate ethylene as they are aged. Reaction mixture components in addition to the sucrose–phosphate buffer are not necessary for the large increase in evolution of ethylene which occurs when aged particles are sonicated; experimental difficulties preclude conclusions as to whether the components actually assist in the production. Ethylene produced by the particles may be bound in some way, and released on further distintegration of the particles. Boiled particles are apparently incapable of this further production of ethylene.

EFFECT OF DIURNAL FREEZE–THAWING ON SURVIVAL AND GROWTH OF SELECTED BACTERIA

By R. S. YOUNG, P. DEAL, J. BELL and J. ALLEN

Exobiology Division, National Aeronautics and Space Administration, Ames Research Center, Moffett Field, California

REPEATED freeze–thawing of micro-organisms is generally considered to be lethal[1,2] unless some protection is provided, such as immersion in glycerol. The experiments reported here demonstrate the ability of some organisms to survive and grow well under freeze–thaw cycles typical of day–night conditions at the equator of the planet Mars in summer. Martian conditions[3] were further simulated in terms of temperature extremes (24° C day to −75° C night) and time cycling. The temperature was cycled so that the organisms had only about 4·5 h during which the temperature was above 0° C with a maximum of 25° C. The remainder of the time was spent in a dry ice chamber at −75° C. In these experiments it was assumed that water is present on Mars, perhaps in some micro-environments, as suggested by Lederberg and Sagan[4], despite the fact that recent observations (unpublished) indicate water in the Martian atmosphere amounting to only about 1 per cent of the Earth's atmospheric water content, and except for the micro-environment possibility, no liquid water at the surface.

Preliminary experiments indicated no effect of simulated Martian pressures (0·1 atmospheres) on growth of micro-organisms so that pressure was not controlled in these experiments. The organisms used were *Aerobacter aerogenes* A.T.C.C. No. 129 and an organism tentatively identified as a pseudomonad collected from the rim of the crater of the volcano Stromboli. Both organisms are facultative anaerobes. *A. aerogenes* was grown on Difco heart infusion broth and the second organism on Difco brain–heart infusion broth. In a typical experiment, sterile broth was seeded with a small quantity of medium from an 18–22 h culture of the given organism grown anaerobically at 25° C. The seeded broth was thoroughly mixed and distributed in 1·5 ml. quantities to a number of 'Pyrex' glass tubes. The tubes were

sealed under nitrogen at one atmosphere by drawing out in a flame. A viability assay was made in duplicate on each of the two tubes immediately after sealing by preparing serial dilutions in broth and plating on solid agar. All experiments were run anaerobically at 25° C. Colony counts were made daily by plating on agar plates. The remaining tubes were placed in a dry ice chamber at −75° C. On the following day, and each day thereafter for the duration of the experiment, the tubes were removed from the dry ice chamber and thawed at 25° C in an incubator. Thawing required approximately 30 min, after which viability assays (in duplicate on each of two tubes) were made at intervals over the next 4·5 h and the remaining tubes were then returned to the dry ice chamber. Control experiments were run using the same technique but without any intervals of freezing.

Fig. 1 shows the results of a typical experiment using *A. aerogenes*. Each datum point on the graph represents an average of four plate counts of two individual experimental tubes. The growing time of the experimental tubes is shown to be approximately 4·5 h per day and the rate of killing due to night-time freezing can be determined. It can be seen that the experimental organisms grow very satisfactorily under these conditions with a fairly constant rate of killing due to freezing. These experiments were repeated several times under identical conditions, always with the same result.

Fig. 2 shows the results of a typical experiment using the organism tentatively identified as a pseudomonad. As can be seen, the results are essentially the same as the *A. aerogenes*. It is of interest to note in these experiments that there appears to be no significant lag phase during the commencement of growth at the beginning of each day-time period, except for the first day. It has also been observed that these two organisms are not unique in this response, but there appear to be others, including yeast, which grow under these conditions. These experiments indicate then the ability of certain of Earth organisms to not only survive but satisfactorily grow under simulated Martian conditions given a suitable medium, including water. The results show a generation time in the experimental bacteria which approaches that

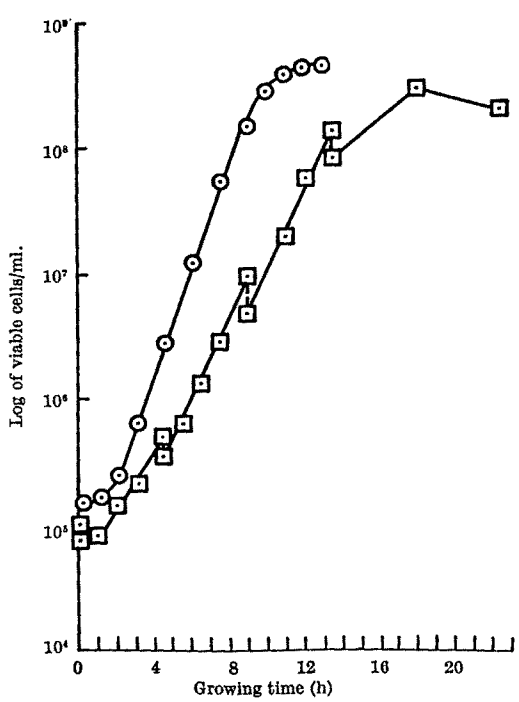

Fig. 1. *Aerobacter aerogenes*
Control, ○, uninterrupted growth; experimental, □, growth interrupted by freezing. Vertical discontinuity illustrates decline in numbers due to death as a result of freeze–thaw process

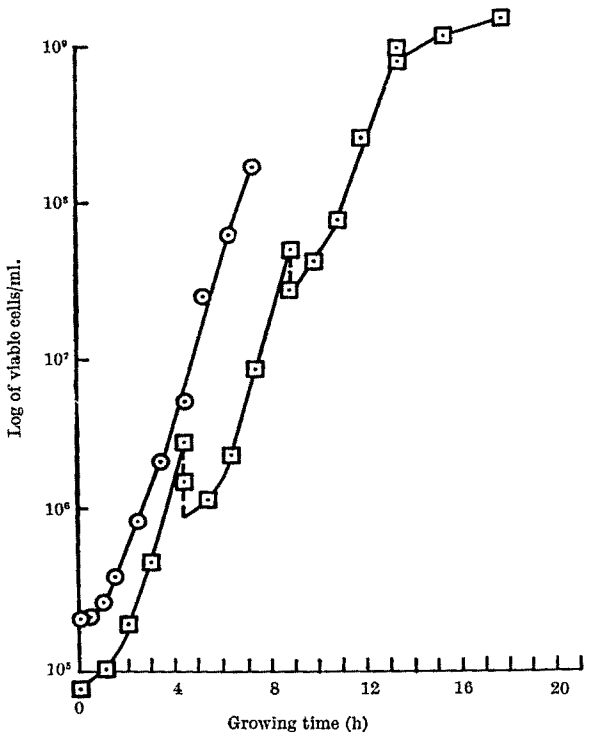

Fig. 2. *Pseudomonas* sp.
Control, ○, uninterrupted growth; experimental, □, growth interrupted by freezing. Vertical discontinuity illustrates decline in numbers due to death as a result of freeze–thaw process

of the controls during the growing period of 4·5 h, so that there is at least a 4,000-fold increase in viable experimental organisms during the 3½–4 days of the experiment, discounting the number of organisms killed by freezing and thawing. The completely lethal effect of repeated freeze–thawing of bacteria and other organisms to be found in the literature is not seen in these experiments and presumably because of the fact that sufficient time is provided for the organisms to reproduce. Preliminary experiments on other bacteria, including one which may be a variant in the *A. aerogenes* culture, show no killing due to freeze–thaw cycling under these conditions. On the other hand, some organisms (*Spirillum itersonii*, *Rhodopseudomonas gelatinosa*, *Pseudomonas ovalis*) tested are killed quickly. Experiments are now being carried out to determine the shortest period of growth time and the minimum nutritional requirements for such organisms to maintain themselves under these conditions.

Experiments are also being performed to determine the minimum water requirements for Earth organisms under simulated Martian conditions. If it can be shown that Earth organisms are able to survive and grow under the most rigorous simulation of Martian conditions possible in the laboratory, this should lend considerable emphasis to the need for space-vehicle sterilization as well as contribute information to our programme aimed at the detection of life on the planet Mars. At the same time, a great deal can be and is being learned concerning the adaptability of life as we know it on Earth to environmental extremes and perhaps, on the mechanisms of adaptation, selection and evolution of organisms on Earth or elsewhere in the universe. Obviously, anything or any conclusions which are made concerning the possible biology of Mars must be made and interpreted with great caution at this time.

ASTRONOMY

A Comparison of Terrestrial and Universal Expansion

Prof. L. Egyed has recently summarized[1] a number of hypotheses concerning the expansion of the Earth, and has suggested that the Earth's radius is expanding at a rate of 0·5–1·0 mm per year.

There appears to be a remarkably close agreement between the rate of increase of the Earth's radius and that of the universe according to Hubble's law. Using the at present accepted value for Hubble's constant, $H = 100$ km/s/megaparsec[2], which is $1{\cdot}65 \times 10^{-4}$ mm per year per mile, and substituting the value of the Earth's radius in the Hubble equation, $v = RH$, we obtain a radial expansion for the Earth of 0·66 mm per year.

While this agreement may be fortuitous it may suggest a fundamental concordance between expansion processes in the Earth's core and those responsible for the expansion of the universe.

ASTROPHYSICS

Change in Rotation Period of Jupiter's Decameter Radio Sources

The hypothesis that Jupiter's decameter radio sources may have a constant period has been widely accepted since its initial independent suggestion by Gallet[1] and by Burke[2]. Estimates of this period have been made by many observers[1–8], and no significant departures from the adopted mean period (System III (1957.0)—9h 55m 29·37s) have been established. Upper limits of ± 2s to yearly fluctuations and of ± 1s to slow secular changes over an eleven-year period, 1950–61, were set by Douglas[7,8] and Douglas and Smith[9]. The apparent constancy of the rotation period, together with a constant difference in longitude between the three apparent activity regions, has supported the hypothesis that the radio sources are related to the non-gaseous body of the planet, perhaps through Jupiter's magnetic field.

Preliminary analysis of 22·2-Mc/s observations made at Bethany Observing Station of the Yale Observatory in 1962 and 1963 indicates that the rotation period of the radio sources has lengthened by approximately 0·8s. This may be demonstrated in two ways. Fig. 1 depicts the number of occurrences of Jupiter activity for each 5° interval of System III (1957.0) longitude of central meridian, for the years 1961, 1962 and 1963 (to July 7). A progressive drift in longitude of the major peak of approximately 10° per year is readily visible, corresponding to a 0·8s lengthening of the period. Fig. 2 is a Whittaker periodogram plot of the same material for a variety of assumed periods. The 0·8s lengthening is clear, and not explainable by statistical fluctuation. A change in the rotation period of the radio sources from approximately 9h 55m 29·4s to approximately 9h 55m 30·2s sometime in 1960–62 is consistent with the observations, a behaviour reminiscent of the abrupt changes in rotation period exhibited by the red spot. Detection of so small an

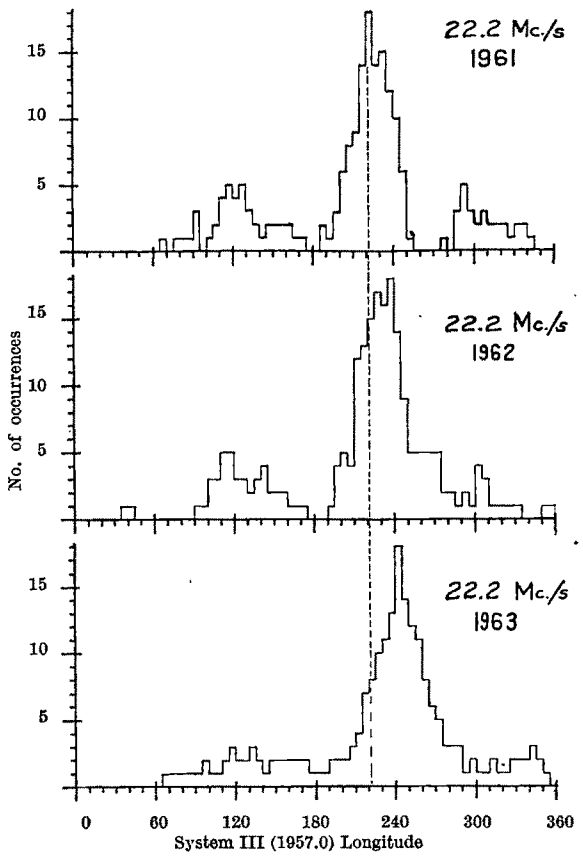

Fig. 1. 22·2-Mc/s occurrence frequency histograms, obtained at the Bethany Observing Station of the Yale Observatory, 1961–63

effect has been made possible by the profusion of Jupiter events recorded in the past three years, due to a substantial increase in Jovian activity, coupled with a new tracking antenna system. Previous period changes of this magnitude or smaller cannot be ruled out, as noted in the limits already quoted. It should be noted that a slow or fluctuating change in rotation period may also be consistent with present observations, as is a change in

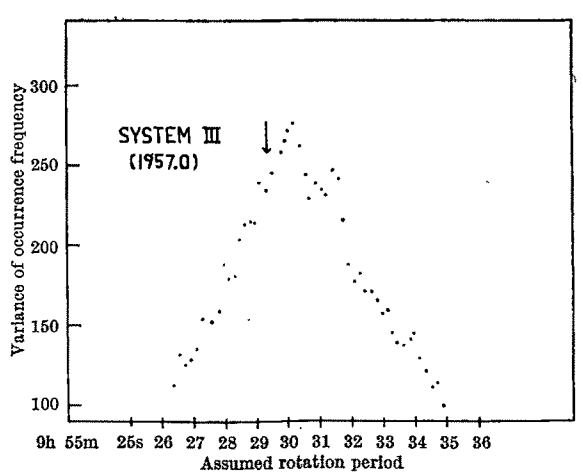

Fig. 2. Periodogram of 22·2-Mc/s Jupiter observations, 1961–63, showing deviation from System III (1957.0) period

apparent longitude of the activity regions; systematic long-term observations are important to clarify the matter.

Hide has hypothesized[10] that the red spot motion refers to that of a solid mantle under a deep atmosphere. In turn, the radio rotation periods may refer to a magnetic field rooted, as in the case of the Earth, to an inner, presumably liquid core. Exchange of angular momentum between core and mantle can then be made evident by studying relative period changes in the red spot and the radio sources[11,12]. Observations of the rocking plane of polarization of the decimetre non-thermal emission from Jupiter can establish the rotation period of the magnetic field. Such observations, as well as optical determination of the current period of the red spot, are now of very great interest, particularly in view of the decametre result reported here.

PHYSICS

A Non-destructive Radioanalytical Method for the Determination of Gallium in Substituted Yttrium Iron Garnets

THE substitution of diamagnetic ions with a valence of three for iron in garnets modifies both the saturation magnetization and the magnetic anisotropy of these materials. So far, there has been no correlation between the extent of the changes in these parameters and the amount of substituted ion. For these reasons and because the amount of garnet material was extremely limited, usually of the order of micrograms, a rapid, non-destructive method for the determination of gallium in yttrium iron garnet was undertaken. The empirical formula of this substituted garnet is $(Fe_{5-x}Ga_x)Y_3O_{12}$, where x is typically in the range of 0·05–0·25.

Attempts to measure the gallium content by X-ray fluorescence methods failed because of the anomalous results obtained between single crystals and powders of the same composition. A non-destructive radioanalytical scheme based on neutron activation and γ-ray pulse-height analysis was developed in this laboratory.

Gallium exists as two stable isotopes, gallium-69 and gallium-71. Thermal neutron irradiation of the former produces the β-emitter (99+ per cent) gallium-70, but because γ-spectrometry was to be used for measurement of the induced activity, it was not of interest in this work. Under the same irradiation conditions, gallium-72 is also formed. Its principal γ-lines are found in good yield at 0·63 and 0·83 MeV; its half-life was found to be 14·2 h, in good agreement with reported values[1].

The spherically shaped, gallium-doped garnet samples weighing from 200 to 300 micrograms were placed in an irradiation container together with a suitable amount of pure gallium metal and a garnet (*YIG*) containing no gallium. Samples and standards were then irradiated in the pneumatic facility of the Massachusetts Institute of Technology Reactor for 1 min at a thermal flux of 8×10^{12} neutrons cm^{-2} sec^{-1}.

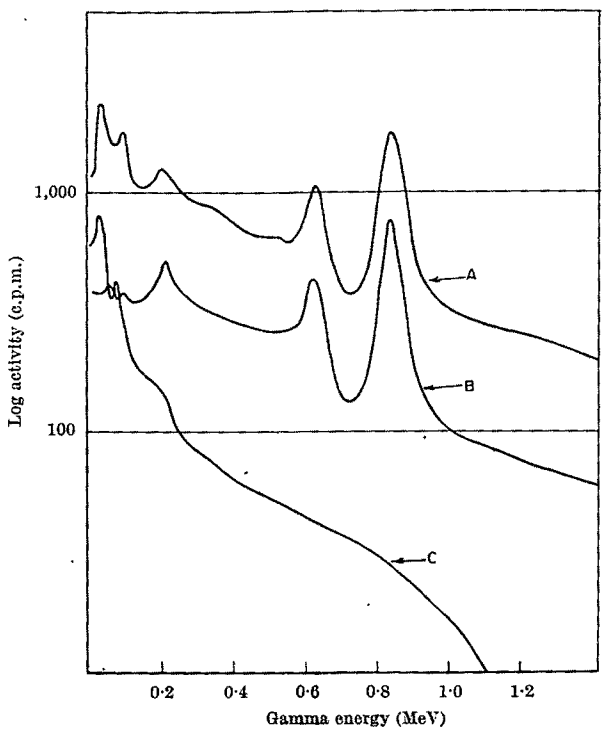

Fig. 1. Gamma spectra of three samples as indicated. Intensities are relative. Spectra taken 4 h after irradiation. *A*, Gallium yttrium iron garnet; *B*, gallium standard; *C*, yttrium iron garnet

The induced γ-activity was analysed for both energy and decay characteristics using a 512-channel analyser coupled to a 2-in. well-type sodium iodide (Tl) crystal detector.

Fig. 1 shows some typical results. The upper curve, *A*, is the γ-spectrum of the gallium-doped garnet. The middle curve, *B*, is that due to the pure gallium metal, and the lowest curve, *C*, is that of the pure gallium-free yttrium iron garnet. The principal peaks in the two upper curves are found to be at 0·63 and 0·83 MeV in agreement with the literature[2] γ-energy values for gallium-72.

Quantitative results are obtained by measurement of the areas under the samples and standard 0·83-MeV peaks after applying the usual background, decay, aliquoting and geometry corrections. An unusual correction, possible because of the versatility of the equipment used herein, was the subtraction of the activity under the aforementioned peak due to the pure yttrium iron garnet. This correction ranged from 2 to 4 per cent. Some results obtained are shown in Table 1.

Table 1. TYPICAL RESULTS OF THE RADIOACTIVATION ANALYSIS OF GALLIUM-SUBSTITUTED YTTRIUM IRON GARNETS

	C.p.m./μg in the 0·83γ peak*	Per cent gallium by weight
Sample *A*	61·5	12·2 ± 0·6
Sample *B*	50·4	10·0 ± 0·5
Sample *C*	47·9	9·5 ± 0·5
Standard	506	

* All corrections applied; time of determination was 4 h after irradiation.

Statistical, weighing, and other known errors amounted individually to less than 1 per cent, and the standard error of the method, given as the standard deviation, is calculated to be not more than 5 per cent.

A search of the literature[3] indicates that no single interfering element or combination of elements could give

a spectrogram with γ-energies and decay characteristics similar to that found.

Finally, it should be pointed out that because of the short irradiation time, residual activity, after a few days decay, is minimal and the garnets may be recovered for additional investigations.

Utilization of Increased Sensitivity of X-ray Fluorescence Spectrometry due to Polarization of the Background Radiation

In X-ray fluorescence analysis, the limit of detection of an element is usually set by statistical fluctuations in the continuous background at the wave-length of the most 'sensitive' line of the element. Consequently, the sensitivity of detection of an element will be improved if the intensity of the continuum is decreased. A typical example is the use of pulse height analysis with a detector the output pulse height of which is proportional to the energy of the incident quantum. By this means, overlapping orders of background can be rejected, resulting in increased sensitivity.

A further improvement can often be made as follows:

The background continuum consists largely of photons which are scattered (both elastically and inelastically) by the sample. Since the angle of scattering accepted by the collimator of typical instruments is about 90°, the scattered radiation is highly plane-polarized[1]. On the other hand, the fluorescent radiation in the line, being emitted some time after the photoelectric absorption of the exciting radiation, is completely random in direction and is unpolarized. Therefore, a marked improvement in line to background ratio could be achieved if one had a polarization analyser.

Such a device is a latent component of most X-ray spectrometers, in the form of the analysing crystal used to disperse the spectrum. Unfortunately, the optics of commercial X-ray spectrometers are usually arranged so

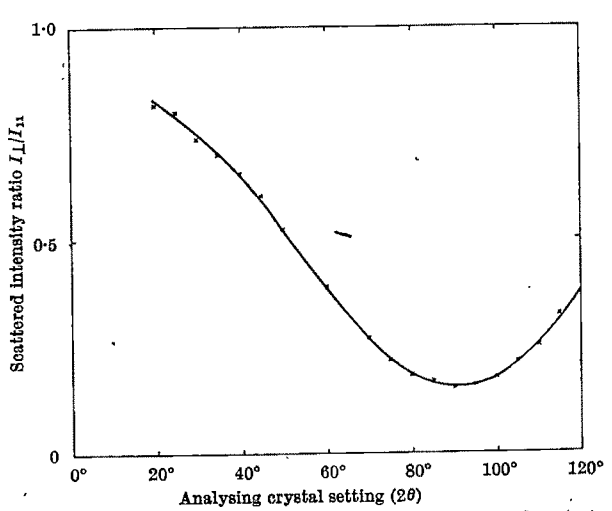

Fig. 1. Ratio of $I_\perp$ to $I_{||}$ of X-rays scattered by water, plotted against angle of tepaz analysing crystal

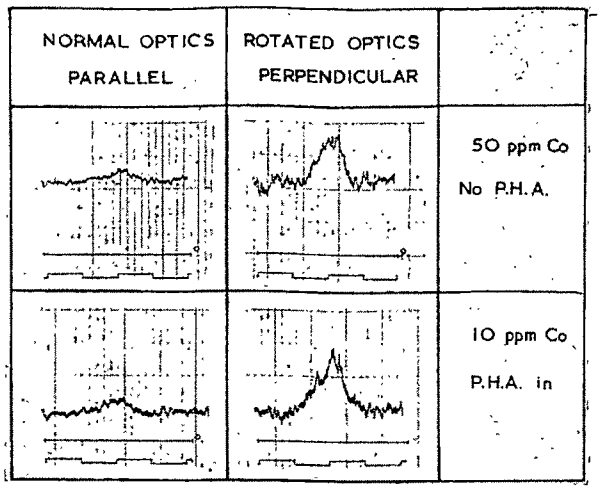

Fig. 2. Traces of cobalt K_α lines using conventional and perpendicular optics

that when the analysing crystal is at its optimum position for polarization ($2\theta = 90°$) the sample and analyser planes are parallel. It is not too difficult with the Philips *PW*1520 instrument to rotate the X-ray tube and sample holder about the axis of the collimator. When these are rotated by approximately 90°, the scattered radiation is considerably decreased for analyser settings in the vicinity of $2\theta = 90°$, as shown in Fig. 1.

The implications in analytical chemistry are illustrated in Fig. 2. The upper pair of traces show the significant improvement of detection of cobalt in aqueous solution (at $2\theta = 82{\cdot}5°$ for a topaz analysing crystal). For comparison purposes, the ratemeter was adjusted to give the same recorder reading for background in both cases.

The lower pair of traces indicates the extreme sensitivity of the method if both polarization of background and pulse height analysis are used.

Influence of Electrode Coatings on Conduction Currents in Transformer Oil

Although the exact mechanism of conduction in dielectric liquids is still the subject of controversy, it has long been recognized that the surface state of the electrodes greatly influences the conduction process[1]. Recent experimental evidence[2,3] has shown that this conduction process is very sensitive to the surface state of the cathode, in particular to the presence of an insulating oxide layer. While it is known that oxide layers on the anode influence the electric strength of liquids[4], the influence of anode surface barriers or films on the conduction currents does not appear to have been studied.

This communication gives some preliminary results of conduction current measurements in transformer oil obtained using direct voltages, with both electrodes bare (*A*), both electrodes coated (*B*), cathode uncoated and anode coated (*C*), and cathode coated and anode uncoated (*D*). Further tests were made in which the coatings on both electrodes varied in thickness (*E*–*G*).

Both the coated and the uncoated electrodes were made of aluminium, polished to a 0·25-μ diamond paste finish. These had a uniform field profile and a nominal diameter of 2·5 cm. The coated electrodes were covered by a pore-free film of the thermoplastic, Penton; thicknesses of 0·5 mm and 0·75 mm were used. The transformer oil

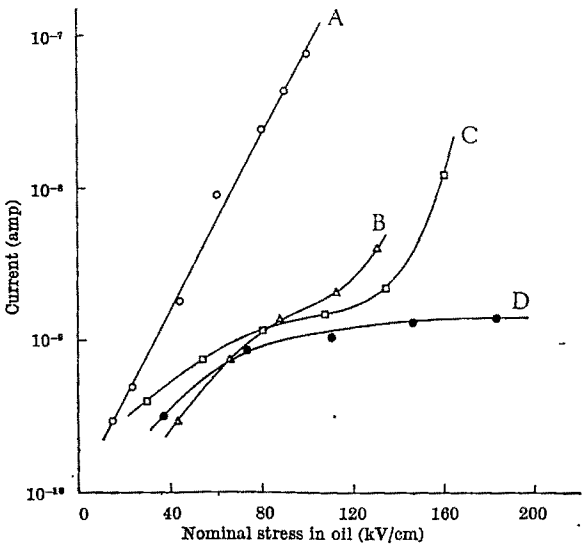

Fig. 1. Typical current–stress characteristics for coated and uncoated electrodes. Oil gap, 1·5 mm; film thickness, 0·5 mm. *A*, Both electrodes uncoated; *B*, both electrodes coated; *C*, cathode uncoated, anode coated; *D*, cathode coated; anode uncoated

was filtered several times through a sintered glass filter of 1-μ porosity. In each test the stress was maintained at a constant value until the gap became conditioned, giving, within the limits of experimental error, steady and reproducible values of current.

Typical experimental results are given in Figs. 1 and 2, the steady current values for each point being plotted to a base of nominal stress in the oil. Curve *A* in Fig. 1 shows that the current with uncoated electrodes increases in a log-linear manner with applied stress, indicating a process of emission. With a film on the cathode only (curve *D*), the emission is greatly restricted and tends to a constant value over the stress range considered. With a film on the anode, irrespective of whether or not there is a film on the cathode, the current, after following an ohmic characteristic at the lower stresses, increases rapidly above about 60 kV/cm.

A tentative mechanism of conduction in oil gaps, indicating the importance of the part played by the anode, is postulated as follows. On the application of voltage, space charges of both polarities are formed in transformer oil[5,6], the positive ions drifting towards the cathode and the negative ones towards the anode. In addition to the negative ions already present in the bulk liquid, electrons emitted at the cathode will form negative molecular ions by attachment. The stability of the negative space charge, and hence its intensity at the anode, will depend on the oxygen content of the liquid and the nature of the anode surface. Thus with air-saturated oil and an insulating film on the anode. a large anode space charge field will be set up giving rise to an ionization process in the vicinity of the anode. Evidence of intense ionization at uncoated anodes in liquids has been reported by Washburn[7] and by Swan and Lewis[4]. Such a process could feed back positive ions to the cathode, further enhancing the field there.

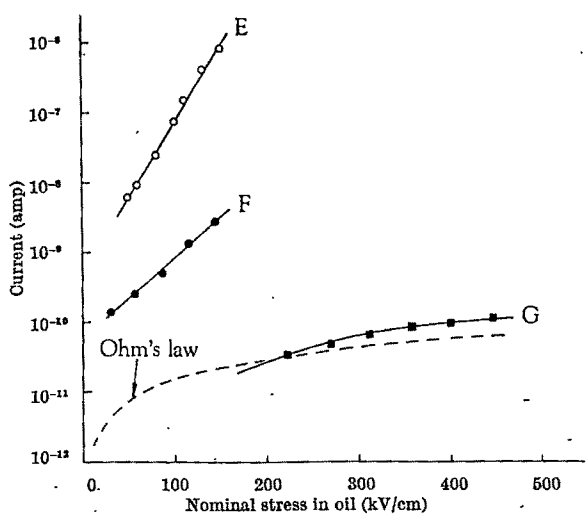

Fig. 2. Variation of current–stress characteristics with film thickness. Oil gap, 1 mm. *E*, Both electrodes uncoated; *F*, electrodes coated with 0·5 mm thick film; *G*, electrodes coated with 0·75 mm thick film

At the cathode two processes acting in opposition are possible: on one hand the presence of an insulating film will decrease emission, while on the other the establishment of a positive ionic space charge leads to a considerable enhancement of the field, resulting in an increased emission. The degree of field enhancement will depend on the number of positive ions available and on the blocking nature of the cathode surface. Hence the emission from the cathode and the formation of positive ions at the anode are interdependent and contribute to the conduction current.

Following the mechanism proposed here, the results given in Fig. 1 may be briefly interpreted as follows: Curve *A* is due mainly to emission from the cathode; the current increase at higher stresses in curve *B* indicates the onset of emission due to greatly enhanced cathode field and intense ionization at the anode; curve *C* is due to cathode emission and ionization at the anode; in curve *D* cathode emission is absent and the ionization at the anode is negligible. By increasing the thickness of the insulating film on both electrodes from 0·5 mm to 0·75 mm, emission from the cathode is almost completely suppressed (Fig. 2).

It has been shown that the presence of an insulating barrier on the electrode surfaces greatly modifies the current–stress relationships which, however, as already shown[3,8], are still characterized by an ionic and then an emission region. Details of this work and a full discussion of the mechanism outlined here will be published elsewhere.

We thank Mr. G. H. Hickling for helpful discussions, the Directors of C. A. Parsons and Co., Ltd., for permission to publish this communication, and Plastic Coatings, Ltd., for supplying the coated electrodes.

Time Characteristics of Light Pulses from Gallium Arsenide Lasers

Recent investigation of the light emitted by gallium arsenide lasers[1–3] when current pulses of widths in the tens of nanoseconds range are passed through the *p–n* junction have led to the observation in this laboratory that a certain charge must flow into the junction before laser action commences. For a given amplitude of the current pulse, there is a corresponding pulse width which will just induce laser action, the laser action commencing

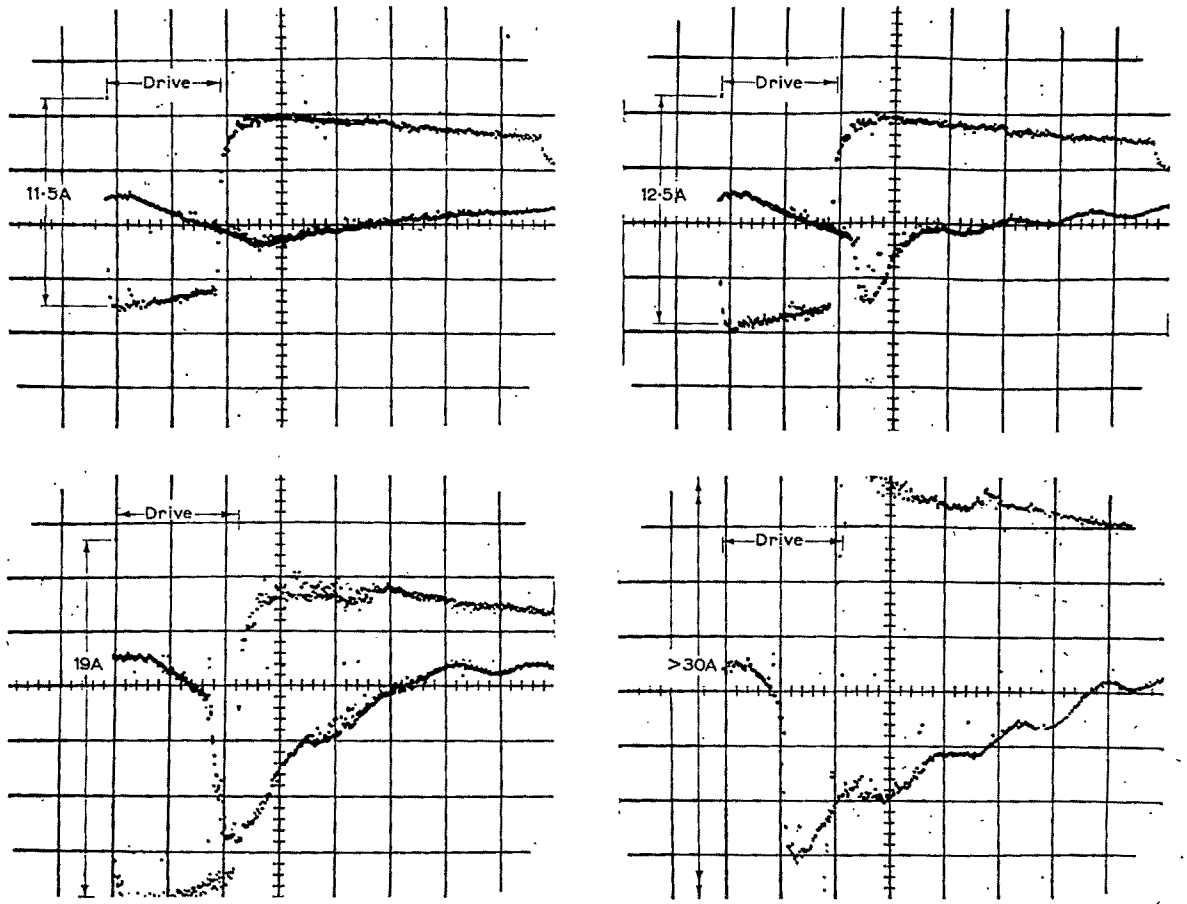

Fig. 1. Top left, no laser action; peak current, 11·5 amp; top right, laser threshold; peak current, 12·5 amp; bottom left, laser action in overdrive condition; peak current, 19 amp; bottom right, laser action in overdrive condition; peak current, >30 amp. In all photographs the upper trace represents the voltage pulse, and the lower trace the light pulse. Time-scale, 50 nsec/cm

on the falling edge of the pulse. The converse is also true. As pulse-width is decreased, the pulse-amplitude must be increased if laser action is to be achieved. Statements that the laser threshold current density under pulse conditions is x amp/cm^2 therefore become meaningless unless the pulse widths at which the measurements were made are also stated. Long time constants have also been observed in the light pulse emitted from the forward biased p–n junction.

The phenomenon is well illustrated by the photographs of oscilloscope traces shown in Fig. 1. The laser was made from n type gallium arsenide doped with selenium to an impurity concentration of 2×10^{18}/c.c., and zinc was diffused into the material to form a p region. The area of the junction was of order 10^{-3} cm^2. Polished faces were cleaved accurately perpendicular to the junction plane to form an optical cavity. The laser diode was operated at 77° K directly immersed in liquid nitrogen. Electrical pulses with rise and fall times of order 1 nanosecond were supplied by a wetted mercury relay-type pulse-generator to the primary of a pulse transformer in the secondary of which were connected in series the laser diode and a non-inductively wound 0·1 Ω resistor. The light pulses were observed using an R.C.A. 7102 photomultiplier with a limited number of dynodes in operation and a load resistor of 100 Ω in the output circuit. The electrical and light pulses were monitored by a Hewlett Packard model 185 A pulse-sampling oscilloscope fitted with a model 1878 dual trace vertical amplifier. Initial observation of the current and voltage pulses across the junction showed that these pulses were in phase and had fast edges.

In Fig. 1 (top left) the light is incoherent, and its pulse has a triangular shape with slow rise and fall times. The time delay between the initiation of the light and voltage pulses is of the order one might expect due to transit time in the photomultiplier (20 nanoseconds), but the maximum light emission occurs at least 10 nanoseconds after the electrical pulse has ceased, and light emission continues over a period several times the duration of the electrical pulse. This long duration of light emission is only characteristic of diode light at high current densities of order a thousand amp/cm^2. At current densities of order a hundred amp/cm^2 the electrical and light pulses have similar widths, and rise times of order 10 nanosecond have been observed on the light pulses.

Fig. 1 (top right) shows the light pulse when laser action commences. The coherent light appears as a peak on the maximum amplitude of the incoherent light, there being a distinct increase of amplitude and a change in the shape of the leading edge of the light pulse. That this was the threshold of laser action was corroborated by inspection with an image converter and a polarizer. The characteristic light spot emitting polarized light just appeared at the same current amplitude as that at which the peak appeared on the incoherent light pulse. Note that the laser action commences at threshold on the falling edge of the electrical pulse. As already observed earlier, this is true for any pulse width if the pulse amplitude is increased until laser threshold is reached.

Fig. 1 (bottom left) shows the light pulses which result when the drive is increased beyond that required to produce laser action. Note that the laser action occurs earlier in relation to the electrical pulse when the drive is increased, and the light peak moves inside the period of the electrical pulse. The decay time of the light pulse is always slow, and occupies a time in excess of the electrical pulse length.

This tail represents a considerable fraction of the total energy in the light pulse in the overdrive condition. It still remains to be established whether this tail is representing mainly stimulated emission or not.

The long time constants involved in the light pulse from the gallium arsenide p–n junction raise fundamental problems on the mechanism of the light emission. More detailed measurements of the phenomenon reported are being made, and the findings will be reported later.

GEOLOGY

Rate of Adsorption of Water Vapour by Degassed Arizona Bentonite

It is perhaps well known that rate data for the rapid adsorption of gases are scarce[1]. What data have been published, moreover, are usually complicated by a varying adsorbent temperature. It would seem that this complication must always be present whenever the rate of adsorption is much greater than the possible dissipation rate of the heat of adsorption. This is the situation in virtually all determinations of very rapid adsorption rates. The only recourse, therefore, appears to be in finding a satisfactory method of analysing rate data for a fluctuating adsorbent temperature. (One must as a consequence in this case simply accept the fact that the temperature coefficient of the adsorption rates will always to some degree be uncertain.)

For some time we have been concerned with the temperature fluctuations accompanying the infiltration of porous media by water[2]. A quantitative description of the heat effects requires an estimate of the differential heat of adsorption (commonly called the isosteric heat of adsorption) of water vapour on the various media as well as the rate of adsorption. We were thus led into adsorption calorimetry and adsorption kinetics. One of our most recent undertakings was a determination of the rapid temperature fluctuation accompanying the adsorption of water vapour by degassed Arizona bentonite. From the result, we have obtained an estimate of the initial adsorption rate.

Arizona bentonite collected at the Cheto pit near Chambers, Arizona, was dried, powdered, and sifted untreated into a small, shallow, plastic dish supported by a thin brass plate in the centre of a cylindrical brass sample chamber. A lead sulphide infra-red radiation detector (Kodak 'Ektron' infra-red detector type Q-2. Time constant: 0·1–0·3 msec at 25° C) was mounted in the heavy brass lid of the sample chamber in such a way that it constantly monitored the temperature of the sample surface. The detector was wired through a sensitive resistance bridge network directly to the deflection plates of a dual trace, single sweep oscilloscope. This made it possible to measure and record photographically the very rapid temperature change of the porous clay surface as a function of time. Degassed, distilled water (about 1 g) contained in a sealed glass vial was placed directly beneath the sample-supporting platform. The clay was degassed under vacuum at 25° C for 24 h at a pressure of 10^{-5} mm mercury, isolated from the vacuum pump, and then exposed suddenly, while still under vacuum, to water vapour by breaking the glass vial. This was accomplished by a suitably arranged brass plunger. The brass sample-supporting plate shielded the clay from the violence of shattering the vial, and subsequent inspection showed that the sample support was also effective in preventing droplets of water from contacting the surface of the clay powder.

The resultant temperature rise was monitored in two ways: by means of the infra-red detector and resultant oscilloscope trace just described, and by means of a 0·001 in. diameter copper-constantan thermocouple embedded in the clay powder. The thermocouple was carefully positioned about 1 mm beneath the sample surface as the adsorption chamber was assembled. Voltages developed across the thermocouple leads were monitored by one trace of the oscilloscope and were afterwards interpreted as temperatures from a previously prepared calibration curve. After the maximum temperature rise had been ascertained by means of the slower responding thermocouple, the oscilloscope trace indicating the response of the lead sulphide detector at this time was interpreted in terms of the maximum thermocouple response. The data shown in Fig. 1 were obtained in this manner.

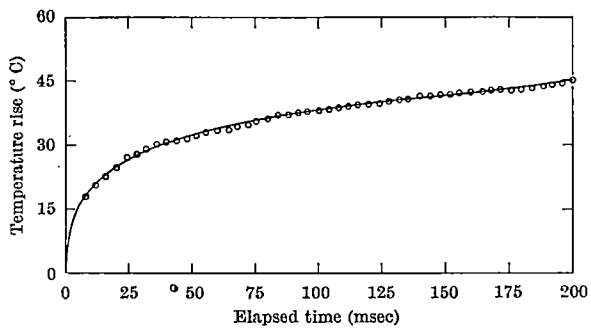

Fig. 1. Rise in temperature during the adsorption of water vapour by Arizona bentonite. Data points are from an oscilloscope trace. The curve drawn through the data was calculated from equation (1)

As can be seen, the rate of temperature rise during the first few msecs was very rapid, amounting to, let us say, about 2,350° C per second. A maximum temperature rise of 50·1° C above ambient (25° C) was observed within about 0·5 sec, after which the temperature declined very slowly. The empirical relation:

$$\Delta T = 50{\cdot}1\ [1 - \exp(-0{\cdot}15t^{0{\cdot}5})] \qquad (1)$$

where ΔT is the temperature rise above ambient in ° C and t is the time (msec), was found to fit the data and is superimposed for comparison in Fig. 1.

An estimate of the rate of adsorption and the sticking coefficient of water vapour on Arizona bentonite may be made by formulating a simple heat balance equation. Assuming that the heat loss from the adsorbent is negligible during the initial stage of adsorption (the loss of heat from the sample at 70° C in the presence of water vapour alone at a pressure of 23 mm mercury was experimentally determined to be about 1·4 cal/sec; this is entirely negligible during the initial rapid adsorption period).

The rate of adsorption is:

$$\frac{dm}{dt} = \frac{c_p}{q_{diff}} \frac{dT}{dt} \qquad (2)$$

in which dm/dt is the rate of adsorption (g water/g clay/sec); c_p is the specific heat capacity (cal/g clay); q_{diff} is the differential heat of adsorption (cal/g water); and dT/dt is the observed rate of temperature rise (° C per sec). Taking $c_p = 0{\cdot}22$, $q_{diff} = 940$ (a value we determined in another experiment during this investigation, the details of which will be published elsewhere), and $dT/dt = 2{,}350$, an initial rate of adsorption of 0·55 g water/g clay/sec is obtained. This corresponds to about $4{\cdot}3 \times 10^{16}$ molecules

per cm² of clay surface area/sec, assuming an external area of 42·4 m²/g clay[3]. The sticking coefficient may be estimated in the usual way[4] as the ratio of the number of molecules sticking to those striking the adsorbent. The latter is approximately $1{\cdot}1 \times 10^{22}$ molecules/cm²/sec, the kinetic theory estimate for water vapour at 25° C, indicating an average sticking coefficient of $3{\cdot}9 \times 10^{-6}$ for the first few msecs. Evidently, roughly all but about one water molecule in every 250,000 striking the clay surface are reflected.

The combination of equations (1) and (2), after differentiating the former with respect to time, leads to:

$$\frac{dm}{dt} = a(t) \exp(-0{\cdot}15t^{0{\cdot}5}) \qquad (3)$$

where $a(t) = 3{\cdot}76\ c_p/q_{diff}\ t^{0{\cdot}5}$ and (after the first msec) is a slowly varying function of time. Here $\frac{dm}{dt}$ has the units g water/g clay/msec.

Equation (3), in some respects, bears a formal resemblance to the well-known Elovich–Taylor–Thon equation for the rate of chemisorption[5]. If the correspondence is more than coincidental, it suggests that the initial stage of adsorption of water vapour by bentonite (probably the hydration of the exchangeable cations[6]) is a chemisorption process. The high initial heat of adsorption (about 17 kcal/mole water) and the low sticking coefficient lend support to this hypothesis.

Occurrence of Karroo System Sediments in Ethiopia

The continental sediments which comprise the Karroo System of southern Africa are formed by thick, dominantly clastic rocks deposited throughout the Palæozoic–Mesozoic transition in a period of general epeirogenic uplift and accompanying cratonic subsidence. Sediments belonging to the Karroo System have previously been recognized as occurring as far north as coastal Kenya, where they are termed the Duruma Sandstone, an essentially continental series of shales and sandstones unconformably overlain by the Mesozoic transgressive marine sediments.

Sediments related to certain members of the Duruma Sandstone and with identical relationship to the Mesozoic marine formations have recently been discovered by Mr. D. H. Jepsen while mapping the geology of the Abbai (Blue Nile) basin for the joint Ethiopia–U.S. Water Resources Board. This information has generously been fully placed in the hands of the author for interpretation. A very brief summary is given here.

Various Italian surveys during the period 1936–40 have shown that previous ascriptions of the Adigrat Sandstone formation to the Karroo System were incorrect. The Adigrat Sandstone is a diachronous facies marking the initial sedimentation phase of the Mesozoic marine transgression from the south-east; although its basal members are not infrequently cross-bedded their conformity with the higher marine sands, mudstones, evaporites and limestones indicates an environment quite distinct from that of the Karroo sandstones.

The sediments discovered by Jepson form two irregularly elongated patches each approximately 5 km × 20 km exposed meridionally across the bottom of the Abbai canyon in the vicinity of the confluences with the Guder and Finchoa rivers. These sediments are overlain unconformably by the planar base of the Adigrat Sandstone and occur in pre-Adigrat valleys aligned north–south in Basement gneiss. These valleys were eroded to a depth of 300–400 m below the peneplained surface of the Basement rocks prior to filling by the pre-Adigrat phase of sedimentation. In the exposures at present known, the upper 150 m of the pre-Adigrat sediments have been removed by the denuding action of the Abbai river.

The remnant 200 m of sediments are composed of mostly thin-bedded bluish-grey calcareous mudstones overlain by massive dark grey sandstone beds. Down-warping of the sediments in the centres of the ancient valleys is considered due to gravitational compaction. The unconformably overlying Adigrat Sandstone, which can be continuously traced from Shoa (where it thickens as it plunges beneath the Rift Valley) to the Sudan border region, is a quite distinct facies; massive, fine to coarse grained, red or buff sandstones with some interbedded variegated shales and thin lenticular beds of conglomerate or pebbly cross-bedded sandstone.

The discovery of proved pre-Adigrat sediments lying on the Ethiopian Basement, a matter previously much disputed, has the following implications: (1) Towards the end of the Palæozoic, an era of peneplanation in the Horn of Africa, there was an uplift of the order of 400 m in central Ethiopia; (2) Consequent on this uplift was the erosion of broad river valleys which were formed meridionally, parallel to the tectonic grain of the foliated Basement rocks; (3) Gradual and accelerating subsidence of the central Ethiopian region enabled a filling of the eroded valleys with sediments derived from an unknown uplifted source, probably to the west; (4) These same epeirogenic tilting movements were perhaps responsible also for the ensuing initiation of the Mesozoic marine transgression north-westwards across Ethiopia, and which reached Shoa by the late Liassic or early Bajocian. The increased supply of sediments was now deposited in a marine environment to form the Adigrat Sandstone.

The occurrence of these pre-Adigrat sediments, probably of Permo-Triassic age considering their relations to the Palæozoic peneplanation and to the Adigrat Sandstone itself, is considered to suggest that Karroo-type sedimentation extended north into Ethiopia, though of restricted occurrence. It is now eminently desirable that these sediments be examined in more detail, particularly their petrography, and that search for fossils be made. It is also necessary that the Waju Sandstone of Chercher, similarly debated as of pre-Adigrat Sandstone age, be re-examined so that a regional knowledge of the existence of Karroo-type sediments over the whole of Ethiopia be obtained.

CRYSTALLOGRAPHY

Structure of α-methyl D-galactoside 6-bromhydrin

As part of a crystallographic investigation of D-galactose and its derivatives, a determination of the structure of α-methyl D-galactoside 6-bromhydrin, $C_7H_{13}O_5Br$, has been carried out. The compound was prepared by Valentin[1] and the unit cell dimensions and symmetry were measured by Cox, Goodwin and Wagstaff[2].

Our measurements were made at 140° K, the crystal being cooled by a stream of dry, cold nitrogen gas provided by apparatus similar to that previously described[3]. The

compound crystallizes as orthohombic tablets, space-group $P\ 2_1\ 2_1\ 2$ with four molecules in the unit cell. We have interchanged the a and c axes given by Cox *et al.* to agree with the convention used in the *International Tables* (1, 104; 1952). The cell dimensions are:

a	At 140° K	11·14 Å	cf. Cox *et al.*	11·23 Å
b		7·815 Å		7·81 Å
c		10·61 Å		10·58 Å

Three-dimensional data was collected using the Weissenberg equi-inclination technique and 1,203 independent hkl reflexions were measured. Patterson projections down the three axes showed that the bromine atom had co-ordinates which were very close to $y=\frac{1}{4}$ and $z=0$ (or $\frac{1}{2}$). Harker sections were then calculated, using the three-dimensional data, and the bromine atom was found to be at $x=\frac{5}{60}$, $y=\frac{14}{60}$ and $z=\frac{1}{120}$. The three-dimensional Fourier synthesis, computed using the phase-angles decided by the position of the bromine atom, had a certain amount of spurious symmetry resulting from the near-special position of the bromine atom. The five most definite peaks were chosen and, together with the bromine atom, were given two cycles of least squares refinement. A second three-dimensional Fourier synthesis was carried out; in this the pyranose ring could be identified, together with a mirror image, and all the remaining atoms with the exception of the carbon atom of the methyl group. Seven cycles of least-squares refinement were then carried out, with isotropic temperature factors, for all the atoms but with the methyl group carbon atom not included. A difference Fourier synthesis then gave the position of the methyl group carbon atom. This atom was introduced into the calculations, together with anisotropic temperature factors for all the atoms and four more cycles of refinement were carried out, the final cycle giving the residual, $R=0{\cdot}108$. The electron density distribution for one molecule is shown in Fig. 1; the contour lines for the carbon and oxygen atoms are drawn at $1e/Å^3$ intervals starting at $1e/Å^3$ and for the bromine atom at $5e/Å^3$ intervals. A diagram of the molecule is shown in Fig. 2. The calculated bond lengths are listed in Table 1.

Table 1. BOND-LENGTHS (Å)

Br–C6	1·974	O1–C1	1·430
C1–C2	1·509	O1–C2	1·448
C2–C3	1·551	O3–C3	1·414
C3–C4	1·502	O4–C4	1·425
C4–C5	1·524	O5–C5	1·461
C5–C6	1·492	O5–C1	1·421

The pyranose ring has the expected chair form with the configuration 1a 2e 3e 4a, exactly as found for β-arabinose by Furberg and Hordvik[4]. In the crystal the bromine

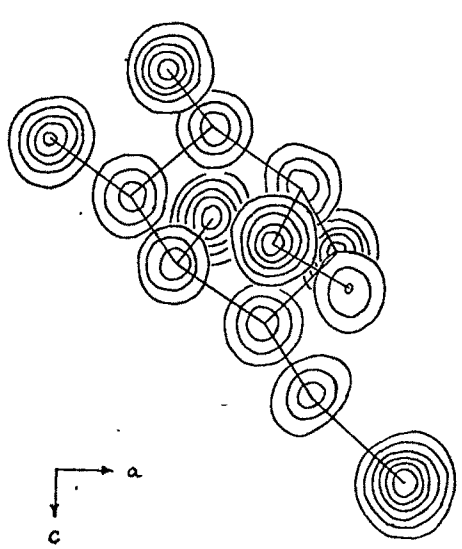

Fig. 1. Electron density distribution

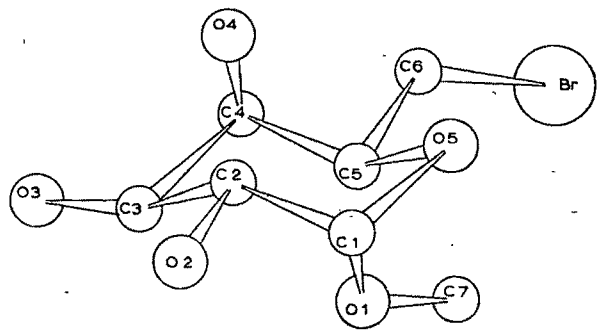

Fig. 2. Stereochemical arrangement

atoms are arranged in sheets parallel to (001), along which cleavage occurs, with the galactose molecules connected to each other by hydrogen bonds. The average carbon–carbon bond length is 1·516 Å and the average carbon–oxygen bond length is 1·434 Å. In previous measurements of sugars having O1 as a hydroxyl group, by McDonald and Beevers[5], McGeachin and Beevers[6], and Furberg and Hordvik[4], the bond between C1 and O1 was found to be significantly shorter than a normal carbon–oxygen single bond; in this work, where the hydrogen atom is replaced by a methyl group, the carbon–oxygen bond distance is quite normal.

The calculations were carried out on the University of Leeds Ferranti *Pegasus* computer and we gratefully acknowledge the use of programmes written by D. W. J. Cruickshank (S.F.L.S.) and by D. W. J. Cruickshank, Diana E. Pilling, A. Bujosa, E. M. Lovell and Mary R. Truter (Fourier synthesis)[7]. We also thank Dr. E. G. Cox for his initiation of this work.

Chain Structure of the *Cyclo*pentadienils of Monovalent Indium and Thallium

THE *cyclo*pentadienils of monovalent indium and thallium have been prepared by E. O. Fischer *et al.*[1,2]. The In-C_5H_5 is very sensitive to oxidation and must be handled in complete absence of air; the Tl-C_5H_5 is more stable and its decomposition follows slowly. The stoichiometric convexion 1/1 between metal and C_5H_5 has been interpreted by E. O. Fischer[2] as a 'half sandwich' structure with transfer of π electrons from the aromatic ring to the metal. On the other hand, F. A. Cotton and L. Reynolds[3] believe the complex to be ionic, on the basis of molecular orbital treatment.

Tyler, Cox and Sheridan[4] have examined the microwave spectra of the gaseous Tl-C_5H_5. The thallium-ring distance is 2·41 Å.

We have examined the single crystals, obtained by sublimation in the vacuum, closed under nitrogen in Lindeman glass of both complexes, and determined the structure by use of two-dimensional Fourier methods on the diffractions of X-rays. The complexes are monoclinic and isotypical; systematic absences were found for hkl with $h+k\neq 2n$; $h0l$ with h and $l\neq 2n$; $0k0$ with $k\neq 2n$.

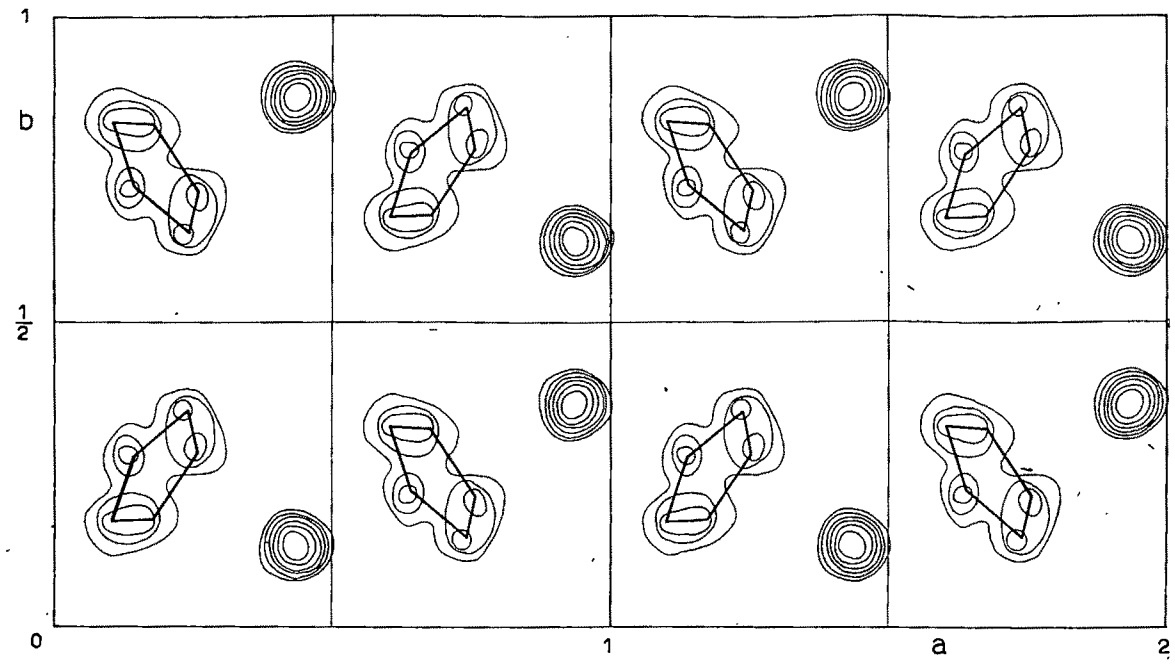

Fig. 1. Electron density projection (001) for indium-C_5H_5. Contours at 2*e*. Å^{-3}. Upper levels for indium omitted

The space group is therefore the non-centrosymmetric monoclinic C_s^4-Cc with four molecules in the unit cell. The lattice constants are listed as follows:

In C_5H_5: $a = 9{\cdot}08 \pm 0{\cdot}02$ Å; $b = 10{\cdot}01 \pm 0{\cdot}02$ Å; $c = 5{\cdot}86 \pm 0{\cdot}01$ Å
$\beta = 102° 30' \pm 30'$ $d = 2{\cdot}30$ g cm^{-3}
Tl C_5H_5: $a = 9{\cdot}13 \pm 0{\cdot}02$ Å; $b = 9{\cdot}96 \pm 0{\cdot}02$ Å; $c = 5{\cdot}94 \pm 0{\cdot}01$ Å
$\beta = 100° 20' \pm 30'$; $d = 3{\cdot}37$ g cm^{-3}

The picnometric density for the thallium-C_5H_5 is $d = 3{\cdot}33$ g cm^{-3}. The picnometric density of the indium-C_5H_5 was not determined owing to the difficulty of handling this compound.

The *h*0*l*, 0*kl* and *hk*0 reflexions for the indium-C_5H_5 and thallium-C_5H_5 were collected with Weissenberg and precession cameras and the intensities read with a photometer fitted with a potentiometric recorder.

Patterson projections were calculated on (001), (010) and (100). Electron density projections were obtained

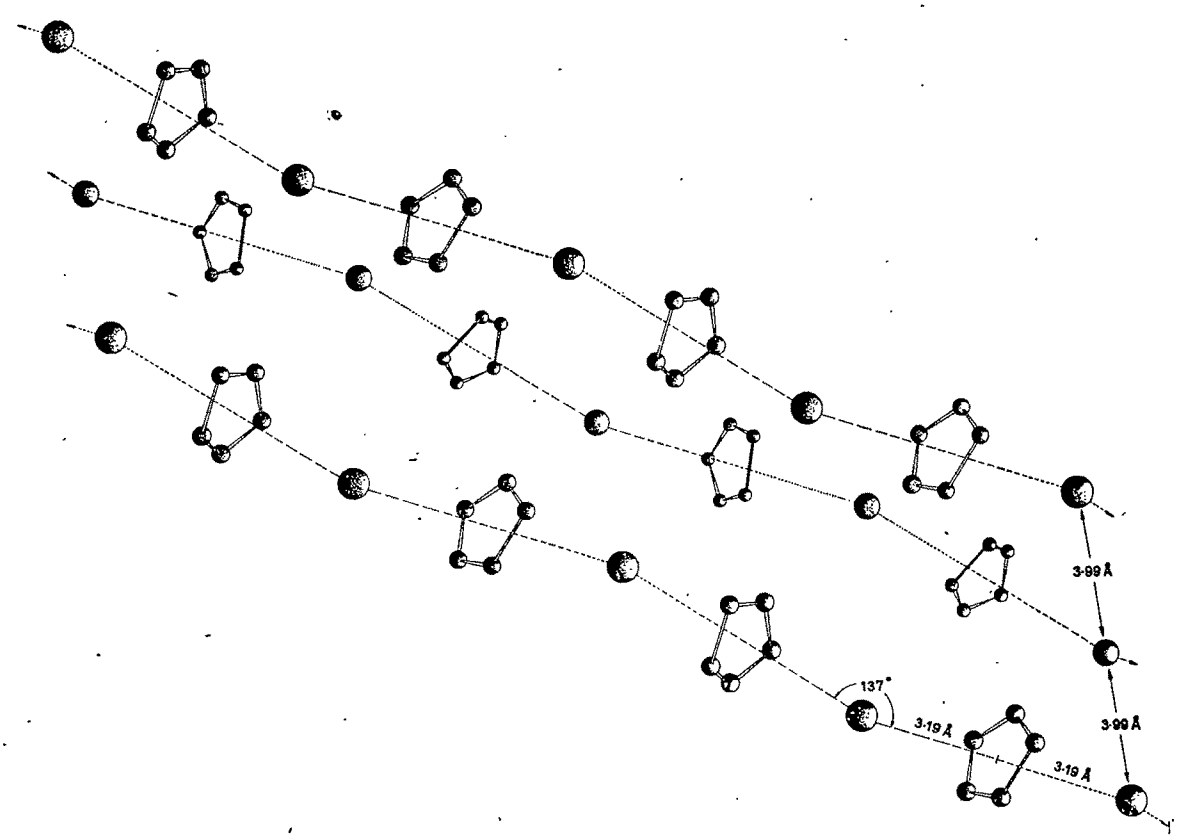

Fig. 2. Packing of the indium-C_5H_5 in the crystal

using at first the heavy atom method. Afterwards the contributions of the light atoms were introduced in the calculated structure factors. Fig. 1 shows the electron density projection on (001).

Both structures are similar, therefore we have chosen the indium-C_5H_5 for successive refinement because the lighter metal-atom would give the possibility of reaching smaller standard errors in the position of the aromatic ring. Using the Cochran method of difference syntheses at the present stage we have obtained the following reliability factors:

$hk0$ reflexions: $R = 0{\cdot}08$, $0kl$ reflexions: $R = 0{\cdot}07$

We have calculated that the actual co-ordinates are affected with the following standard errors:

In: $\sigma_r = \pm 0{\cdot}01$ Å and C: $\sigma_r = \pm 0{\cdot}07$ Å

The packing of the molecules in the crystal can be better explained with the aid of Fig. 2, where three chains of molecules are partially represented.

The structure is characterized by a chain disposition of the metal atoms and of the rings enclosed between them, at the same distance from both metals. The angular disposition of the system ring-metal-ring is characterized by an angle of $137° \pm 30$ min at the metal. The metal-ring distance is $3{\cdot}19 \pm 0{\cdot}10$ Å. The packing of the chains allows a minimal distance of 3·99 Å between metal-atoms belonging to adjacent chains. As can be seen, there is a zig-zag of equidistant metal-atoms, the angle M–M–M being about 100°.

The difference between the metal–ring distances in the gas phase[4] and in the solid-state is very large. This difference determines a great change of structure: in the gas phase there is the monomeric 'half sandwich' structure formed by one metal-atom and one aromatic ring; in the solid phase there is a polymeric structure formed by zig-zag chains. The chains are held together by a zig-zag of metal-atoms: the metal-metal distance is such as to allow the possibility of interaction between them.

It should be noted that every metal-atom is surrounded by two rings with the geometrical characteristics of the angular 'sandwich' structure.

The polymeric character explains the insolubility of the complex noted at first by E. O. Fischer.

CHEMISTRY

Anhydrous Ruthenium Chlorides

The contrasting magnetic behaviour (Table 1 and Fig. 1) of the α- and β-forms of $RuCl_3$ is of interest in relation to the different types of stereochemical arrangements[1] shown by the transition metal halides: it has also allowed the presence of α-$RuCl_3$, produced in the usual method of preparation of β-$RuCl_3$, to be detected. A material, hitherto considered[2,3] as yet another form of $RuCl_3$, is now shown to be $Ru_2^{IV}OCl_6$ (Table 1), a member of a class of oxide chlorides of binuclear ruthenium in which the average oxidation state of ruthenium changes from +4 through +3·5 to +3.

α-RuCl₃. This is produced[3,4] by a slow reaction between the metal and chlorine in siliceous vessels at temperatures above 600° C. However, contact of the metal with the silica causes the α-$RuCl_3$ to be contaminated with the soluble and relatively volatile oxide chloride, Ru_2OCl_6 (since this is diamagnetic its presence lowers the susceptibility observed and accounts for the values previously reported[5] being 16–19 per cent lower than ours). To avoid this contamination, α-$RuCl_3$ has now been prepared by heating β-$RuCl_3$ at or above the transition temperature for the β → α transformation. We have found, using the susceptibility as a means of analysis, that this transformation occurs slowly ($t_{\frac{1}{2}}$, about 1 h) at about 450° C, a temperature appreciably lower than the > 500° previously noticed[4]. The molar susceptibility, χ_M, of α-$RuCl_3$ between 77° and 300° K is shown in Fig. 1; at very low temperatures it decreases:

Temperature (° K)	77·3	20·4	4·2
$\chi_M \times 10^6$, E.M.U.	9,500	15,400	9,950 (all ± 200)

suggesting that α-$RuCl_3$ becomes antiferromagnetic. Neutron diffraction measurements (by G. E. Bacon) at 4·2° K confirm this behaviour and indicate a small magnetic moment (about 0·2 *B.M.*) on each ruthenium atom. The Néel temperature, T_N, about 30° K, is of the same order as those, 17° and 15° K respectively, reported[6] for $CrCl_3$ and $FeCl_3$.

Table 1

Compound	Appearance	Solubility	Magnetic behaviour	Structure
α-$RuCl_3$	Black, lustrous	Insoluble	With $A = 1{,}000$ cm^{-1}, μ_{eff} is 2·14 B.M. at 300° K, and θ is 32–40°. Antiferromagnetic, T_N, about 30° K	Hexagonal, layered (ref. 4); $a = 5{\cdot}99$, $c = 17{\cdot}22$ Å. Ru atoms have octahedral bonding with d_ε^5 configuration
β-$RuCl_3$ (metastable)	Dark-brown fluffy	Soluble in EtOH	χ_M low and decreases as temperature falls (Fig. 1)	Hexagonal, layered; $a = 6{\cdot}12$, $c = 5{\cdot}66$ Å. Ru atoms probably have tetrahedral bonding with $d_\gamma^4 d_\varepsilon^1$ configuration.
Ru_2OCl_6	Dark-brown hygroscopic	Soluble in H_2O and EtOH	Diamagnetic	Probably linear Ru—O—Ru, cf. $[Ru_2OCl_{10}]^{4-}$

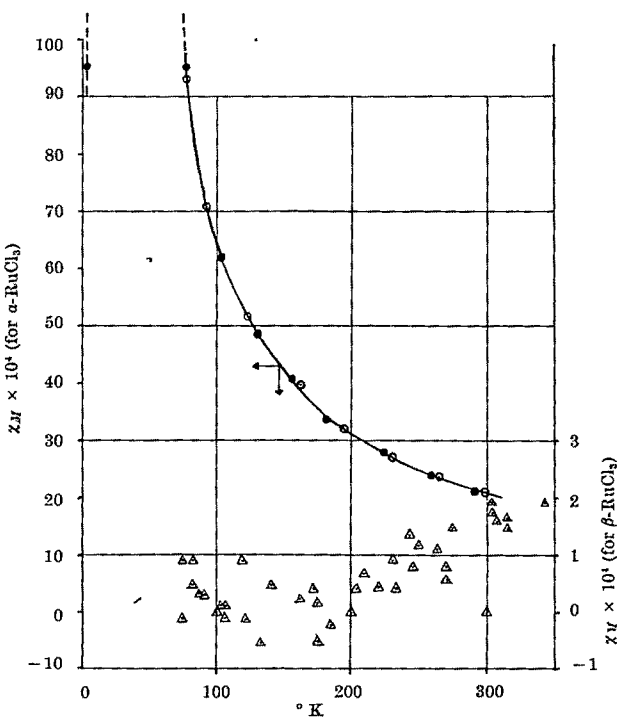

Fig. 1. Observed molar susceptibilities: ⊙, ●, Results for two separate preparations of α-$RuCl_3$; △, results from five separate sets of measurements between 77° and 345° K on the same preparation of β-$RuCl_3$, heated for 4 h at temperatures between 400° and 440° C between each successive set of measurements

β-*RuCl*$_3$. This is made[7] by heating ruthenium metal in a stream of carbon monoxide and chlorine. The susceptibilities of preparations made at 360°–390° C indicate the presence of 10–15 per cent of α-$RuCl_3$; this was not detected in the X-ray patterns until the materials had been annealed. β-$RuCl_3$ (found: Ru, 48·3; Cl, 50·5 per cent), almost free from α-$RuCl_3$ and certainly free from residual metal, has therefore been made at a temperature (340° C) lower than formerly used but sufficiently high for the carbonyl intermediate, probably $Ru(CO)_2Cl_2$, to be absent. The small increase in the observed susceptibility below 100° K (Fig. 1) is attributed to a trace (< 2 per cent) of α-$RuCl_3$ in the sample.

Oxide Chlorides. Ru_2OCl_6 is one of several relatively volatile oxide chlorides which can be formed from the water-soluble mixture of aquochloro complexes[8] of polynuclear Ru(IV) known as "commercial ruthenium trichloride". This, when dried at 110°, consists largely of $(Ru_2O)^{6+}$ complexes, and after further heating at 300° in a stream of chlorine, leaves a dark-brown hygroscopic residue, mainly Ru_2OCl_6. Such a residue had a chlorine/ruthenium ratio of 3·04; the average oxidation state of ruthenium was +3·96; and the absorption spectrum of a solution in 1 N acid, had λ_{max} 390 mμ, $\varepsilon_{Ru} = 5{,}600$, characteristic[8] of Ru_2O^{6+} complexes. It appeared amorphous to X-rays and was diamagnetic. When, however, the heating at 300° is carried out in a vacuum instead of a stream of chlorine, other oxide chlorides, Ru_2OCl_5 and Ru_2OCl_4, which have ruthenium respectively in the +3·5 (ref. 9) and +3 oxidation states, are formed. A typical product had the ratio chlorine/ruthenium = 2·60, and an average oxidation state of + 3·74: these, together with the spectrum of its solution, indicate a mixture of the following mole fractions: 0·62 Ru(IV) as $(Ru_2O)^{6+}$, 0·06 Ru(IV) as RuO_2, 0·22 Ru 3·5 as $(Ru_2O)^{5+}$, and 0·10 Ru(III) as $(Ru_2O)^{4+}$. The material was paramagnetic, χ_g being $0{\cdot}74 \times 10^{-6}$ e.m.u. at 299° K and rising to 1·57 at 90° K. The brown hygroscopic substance observed[2,3] to accompany α-$RuCl_3$ when prepared from the metal and chlorine at 600°–700° C was identified as Ru_2OCl_6 by the absorption spectrum of its aqueous solution and by the oxidation state of ruthenium.

Interpretation of Susceptibilities. The layered structure and cell dimensions[4] (Table 1) of α-$RuCl_3$ imply that each ruthenium atom occupies a position in which it is bonded octahedrally to six chlorine atoms. We assume: (1) that a strong ligand field exists for Ru^{3+} in the compound giving it a d_ε^5 configuration; (2) that there is a fairly strong spin-orbit interaction[10,11], such that the coupling constant, A (in ° K), is $> T$. It then follows[10] that $\mu^2_{eff} = 3 + 8T/A$ and that $\chi'_M = \dfrac{3 + 8T/A}{8(T - \theta)}$, where θ is a measure of the net magnetic interaction between the ruthenium ions. Although A for Ru^{3+} has been assessed[1] at 2,250° K, results[12] for Ru(III) complexes (for which θ should be nearly zero) give values in the range 1,000–2,000° K. Substituting $A = 1{,}500°$ K (≡ 1,000 cm^{-1}), and adjusting the values of χ_M to χ'_M by adding 100×10^{-6} e.m.u. for the diamagnetism of the ion cores, it is found that θ is 40° at 300° K and decreases to about 32° at 80° K (cf. θ = 31° for $CrCl_3$) (ref. 13). μ_{eff} is 2·14 Bohr magnetons at 300° K. The positive value of θ implies that the antiferromagnetic coupling between the ruthenium atoms in adjacent layers is weak compared with the ferromagnetic coupling between the ruthenium atoms within a layer.

The low values of χ_M shown by β-$RuCl_3$ are explained by each ruthenium atom occupying a position in a layered structure where it is bonded tetrahedrally to four chlorine atoms: this configuration may well be favoured by a 4-co-ordinated complex, $Ru(CO)_2Cl_2$, being an intermediate. On Kotani's[10] theory, Ru^{3+}, when tetrahedrally bonded and spin-paired, takes a $d_\gamma^1 d_\varepsilon^1$ configuration and, provided again that $A > T$, its magnetic moment is low, μ_{eff} being given by $\sqrt{4\ T/A}$ and χ'_M by $[2A(1-\theta/T)]^{-1}$: using again the value of 1,500° K for A, χ'_M would be $\sim 330 \times 10^{-6}$ e.m.u. at 300° K. In fact, χ'_M (that is, $\chi_M + 100 \times 10^{-6}$ e.m.u.) for β-$RuCl_3$ is found to be about 280×10^{-6} e.m.u. at 300° K. The fall in χ_M (Fig. 1) and hence in χ'_M as the temperature is lowered implies that θ in this case is negative, but a reasonable value for θ does not account for the observed fall.

It appears that β-$RuCl_3$ is metastable, the β→α transformation being exothermic[4] and irreversible, and its density[4] being lower than that of α-$RuCl_3$.

We thank Miss M. Jones for certain analyses, Mr. J. Penfold for the susceptibility measurements at low temperatures, and Prof. P. L. Robinson for discussions.

Electron Spin Resonance in Polymer Carbons: Effect of Halogens and Interhalogen Compounds

The effect of adsorbed gases on the electron spin resonance signals of amorphous carbons has been reported by a number of workers[1–3]. In general, it has been found that whereas gases such as H_2, Ar, N_2 and Cl_2 (ref. 4) have no effect on the resonance signals, paramagnetic gases such as O_2 and NO have been found to have a large reversible effect at room temperature. This behaviour has been ascribed to the magnetic properties of the paramagnetic gas molecules.

Recent work in these laboratories has shown that the electron spin resonance signals of certain polymer chars are considerably modified by the adsorption of halogens and interhalogen compounds on to the carbon surface. Thus the adsorption of iodine from solution or from the vapour phase at room temperature by carbons prepared from polyvinylidene chloride (in the heat treatment range 300–1,000° C) caused a marked reduction in spin concentration at almost constant line width. The original signal was not restored by outgassing the carbon specimens at room temperature, but could be partially recovered by reheating the specimens in vacuum to 100° C.

The effect of Cl_2 and Br_2 was similar to that of I_2, leading to a partial or complete reduction in spin concentration depending on the carbon examined. In the reaction with chlorine at room temperature hydrochloric acid was detected in the gas phase using infra-red methods.

It should be noted that these effects are not observed with all amorphous carbons, a fact which may be explained on the basis of some of our earlier work[5], in which it was

shown that the reaction of paramagnetic oxygen molecules, with the unpaired electrons of the carbon, may be used as an indicator of the porous nature of the carbon structure. We found that carbons prepared from polyvinyl cyanide have negligible surface area, and as they are virtually inaccessible to gas molecules, show no characteristic electron spin resonance effects with paramagnetic gases. We attribute the failure of earlier workers to observe any effect with halogens to the inaccessibility of the carbons examined. This idea is supported by the observation that a polydivinyl benzene carbon (heat treatment temperature 900° C), initially showing no halogen effect, was found to have the signal partially removed after development of pore structure by activation with carbon dioxide at 880° C.

On the basis of our preliminary results we tentatively suggest that halogens adsorbed by a suitable carbon will interact with the unpaired electrons giving rise to some type of charge transfer complex. This has already been suggested as[6] possibly occurring in the adsorption of molecular oxygen by amorphous carbons. The formation of such charge transfers or molecular complexes between aromatic molecules and halogens is well established[7,8] and in many cases strong electron spin resonance spectra have been observed[9,10]. It is thought that the apparent disappearance of unpaired electrons in amorphous carbons occurs for the same reason as their production from initially neutral organic molecules, that is, an intermolecular charge transfer between the carbon and the halogen occurs, resulting in the removal of the unpaired electron from the carbon, and the formation of a complex which no longer exhibits electron spin resonance.

This could possibly arise as a result of a broadening of the resonance line beyond detection when the unpaired electron is localized on the iodine molecule. It has been observed that the charge transfer complexes between oxygen and aromatic molecules[11] show electron spin resonance spectra characteristic of the Ar^+ ion, but non-corresponding to the O_2^- ion. Similarly, Bennett *et al.*[12] have shown that the O_2^- ion in superoxide has an extremely broad resonance line. However, it should be noted that irradiation of potassium chloride crystals doped with potassium iodide produced a narrow electron spin resonance line which has been attributed to the I_2^- ion[13] though we feel the two systems are so different as not to allow any reasonable comparison.

The stability of charge transfer complexes of halogens and interhalogen compounds with organic molecules depends on the relative electron acceptor strengths of halogens, and decreases in the order $ICl > IBr > I_2 > Br_2 > Cl_2$ (ref. 14). We have been able to show that ICl and IBr produce analogous effects to I_2, though no estimate of the relative stability of the complexes has been made.

In the case of hydrogen containing chars, the stability of the complexes will also depend on the ease with which the halogen can react further with the hydrogen sites. Iodine, owing to its high electron acceptor strength and low affinity for hydrogen, might be expected to form a stable charge transfer complex. Chlorine, on the other hand, having a much greater affinity for hydrogen and low electron acceptor strength, will be more likely to react via the charge transfer complex with adjacent hydrogen sites producing hydrogen chloride, chemisorbed chlorine, and a regeneration of the signal in the absence of excess chlorine.

For certain carbons there is experimental evidence for believing this to occur, the chlorine being unable to react with the spin sites to affect the resonance either because the concentration of molecular chlorine is too low or because of pore restriction by chemisorbed chlorine.

If one assumes that the unpaired electrons in carbon represent sites of abnormally high reactivity, then the removal of these sites by the formation of a charge transfer complex may be the reason for the reported inhibition of graphite oxidation by chlorine[15].

Action of Mercuric Chloride on Strained Keratin

Further evidence that the strained disulphide bonds of stretched animal fibres are more reactive than unstrained bonds has been obtained in experiments with mercuric chloride. Purified human hair fibres of measured cross-sectioned area were immersed in a solution of mercuric chloride (0·1 M) in hydrochloric acid (0·1 N) for 24 h at 22·2° C and then stretched different amounts in the same medium. After being released, the fibres were washed for 7 days in running water before their load/extension curves were determined up to the breaking point in distilled water at 22·2° C. Values for the work required for 55 per cent extension were derived from the load/extension curves and give the lower curve in Fig. 1.

For reference purposes, other fibres were stretched twice in distilled water, and it is because such fibres normally break at 55 per cent extension, whereas fibres stretched in the solution of mercuric chloride have higher extensions at break, that the work was calculated for this extension in all cases. Comparison of the two curves of Fig. 1 shows that the fibres are weakened far more by extension in the mercuric chloride solution than in water, and since fibres which had been immersed in the mercuric chloride solution for 24 h at 22·2° C, but without extension, were found after prolonged washing to give load/extension curves which were almost identical with those of untreated fibres in water, it seems probable that

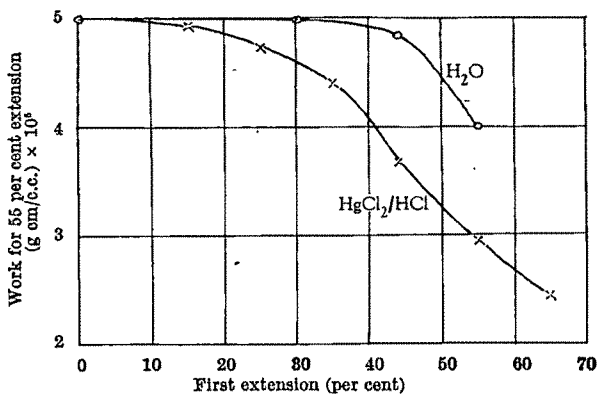

Fig. 1

the weakening is brought about by the fission of strained disulphide bonds according to the reaction:

$$R - S - S - R + HgCl_2 \rightarrow RSCl + RSHgCl \text{ (ref. 1)}$$

This view is supported by the higher extension at break of fibres stretched in the mercuric chloride solution, as well as by the general similarity between these results and those obtained with fibres which were stretched in presence of adsorbed iodine[2]. In both cases the breakdown occurs mainly in those regions of the fibre which give the higher modulus of the third part of the load/extension curve.

BIOCHEMISTRY

Examination of Optically Excited Amino-acids by Electron Spin Resonance at Very Low Temperature

We have recently[1] investigated the irradiation by ultra-violet light of amino-acids at low temperature. Preliminary results of an investigation by electron spin resonance were given. We mentioned the difficulties of a correct interpretation of the signals obtained on microcrystalline powders of phenylalanine and tryptophan. Here are the first results of an investigation concerning solutions of aromatic amino-acids (tryptophan, phenylalanine, tyrosine).

At low temperatures transparent glasses are obtained with certain solvents. The purified and degassed samples are directly irradiated in the cavity of a Varian 4502 02 spectrometer at the liquid nitrogen temperature. The source of light is an Osram *HBO* 200 lamp without filter. There is a great difficulty in obtaining sufficiently concentrated solutions as the solubility of these amino-acids in ether–pentane–alcohol (EPA) is very low. But it can be raised by addition of alcohol and thus it is possible to obtain an electron spin resonance signal with tryptophan for $g \simeq 2$ after a few minutes of irradiation.

But the following results show that the signal is not specific of the solute because there is certainly a photosensibilization of the alcoholic part of the solution. Alcohols alone give better solubility (10^{-2} M with methanol, ethanol). Great care must be taken in avoiding crystallization. Two kinds of electron spin resonance signals are then obtained.

Electron spin resonance signals of the triplet state of phenylalanine, tyrosine and tryptophan. We know[2] that it is possible to induce a resonance transition corresponding to $\Delta m = 2$ in several organic molecules; Smaller succeeded

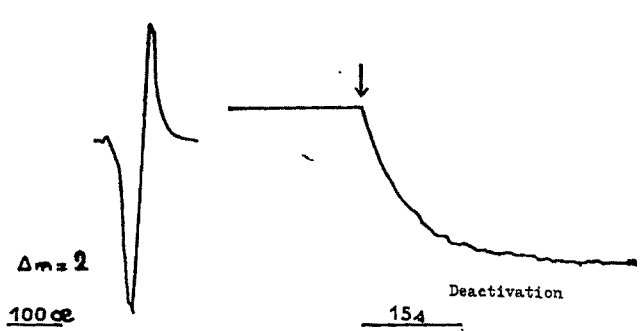

Fig. 1. Triplet state of tryptophan in methanol at low temperature

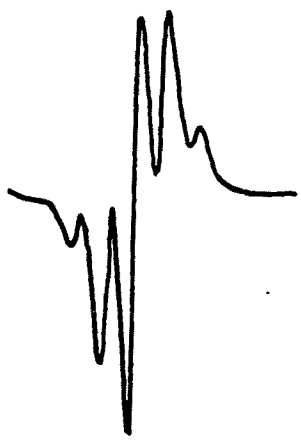

Fig. 2. Electron spin resonance signal of photosensibilized methanol

in investigating the triplet state of indole[3] and benzene[4] by electron spin resonance.

With these three amino-acids in alcoholic solution, at low temperature, we obtained signals which are specific of the state $S = 1$ (Fig. 1). Their form, position and deactivation kinetics are characteristic of the molecule considered. More information will be available with the complete calculation of the spin Hamiltonian.

Electron spin resonance signals of free radicals produced with solvents. For the normal transition $\Delta m = 1$, intense signals are obtained, and if we investigate their structure we can make the following conclusion: for sufficient concentrations of amino-acids we observe the photosensibilization of the alcohols by appearance of free radicals (Fig. 2).

The nature of these radicals, their appearance kinetics, their development with temperature are quite complex[5]. In the first seconds of irradiation we have a rather weak signal, similar to that of the methoxy CH_3O radical. Then it grows notably in intensity and complexity, giving a signal which must be that of the CH_2OH and CHO radicals. Smaller observed similar reactions with indole solutions in methanol.

In conclusion, it is difficult to make out the existence of radicalar metastable configurations in amino-acids by electron spin resonance. With new experimental conditions we might be able to obtain a characteristic electron spin resonance signal of the solute and to give its right interpretation.

Recent results of Gill and Weissbluth[6] on the thermoluminescence of polycrystalline samples of amino-acids induced these authors to admit the existence of such metastable configurations. But the results obtained in the same time by electron spin resonance are much more delicate to analyse. This conclusion and our observation of a triplet state pose the problem of the relationship between the triplet and the metastable states of the molecules of aromatic amino-acids: we are now investigating this matter.

Inhibitory Action of Adenine, Adenine Nucleosides and Nucleotides on the Biosynthesis of Porphyrins by *Rhodopseudomonas spheroides*

Our earlier investigations have shown that adenosine-5-monophosphoric acid (AMP) exerts a strong inhibitory action on excess porphyrin formation in rats with experimental porphyria[1,2] or in lead-poisoned rabbits[3] as well as *in vitro* during incubation of reticulocytes or liver homogenates of rabbits with glycine[4]. Rimington has also observed this effect of AMP in the porphyria induced in rats by hexachlorobenzene[5]. To obtain further results concerning this inhibition, we have investigated the effect of adenine, adenine nucleosides and nucleotides on the biosynthesis of porphyrins by *Rhodopseudomonas spheroïdes*. As it is known, this micro-organism synthesizes, in semi-anaerobic conditions and in the light, porphyrins (and bacteriochlorophyll) through the same biochemical mechanism as animal cells.

Rhodopseudomonas spheroides, obtained from Dr. Lascelles (Oxford), were grown semi-anaerobically in the light at room-temperature for 48 h in medium *S* of Lascelles[6]. Then, the organisms were gathered by centrifugation at 0° and washed with cold 0·05 M phosphate buffer $pH = 7{\cdot}4$. The washed cells were suspended at a final concentration of 0·2–0·8 mg/ml. either in mixture *I* of Lascelles (containing α-oxyglutarate and glycine), or in mixture *Ia* of Lascelles (containing succinate and glycine), or in mixture *II* of Lascelles (containing δ-aminolævulinic acid as substrate). The adenine nucleosides and nucleotides were added in various amounts. These different mediums were then exposed to the light in semi-anaerobic conditions for 48 h. After this time, the dry weight of micro-organisms was determined by the method of Cohen-Bazire *et al.*[7]; porphyrins and bacteriochlorophyll were extracted and measured respectively following the methods of Lascelles[6] and Cohen-Bazire *et al.*[7].

Adenine, adenosine, inosine, AMP, ADP and ATP, at a concentration of 3 mM, exerted an inhibitory action in mixture *I* on porphyrin synthesis. Inhibition was weak for adenine, of about 50–70 per cent with adenosine, inosine, AMP and ADP, very strong with ATP (Table 1). The growth of the micro-organism and the formation of bacteriochlorophyll were not significantly modified by these compounds, except adenosine which inhibited constantly the synthesis of bacteriochlorophyll. Thus the decrease in porphyrin concentration after incubation in the presence of the investigated compounds cannot be explained by an increased synthesis of bacteriochlorophyll.

Table 1. Effect of Adenine, Adenosine, Inosine, AMP, ADP and ATP on Growth and Synthesis of Porphyrin and Bacteriochlorophyll in Mixture *I* of Lascelles (Incubation, 48 h)

Medium	Dry weight of micro-organism (mg/ml.)	Porphyrin (μmM/ml.)	Bacteriochlorophyll (μmM/ml.)
Mixture *I* of Lascelles	1·2	36·9	1·69
Same mixture + adenine, 3 mM/l.	1·1	29·5	1·25
Same mixture + adenosine, 3 mM/l.	0·9	14·6	0·84
Same mixture + inosine, 3 mM/l.	1·2	19·3	1·65
Same mixture + AMP, 3 mM/l.	1·2	7·9	1·35
Same mixture + ADP, 3 mM/l.	1·0	10·9	1·40
Same mixture + ATP, 3 mM/l.	1·1	0·5	1·35

The inhibitory effect has been also observed in mixture *Ia* (Table 2). Here again, ATP exerts the strongest inhibition.

The relation between the concentration of purine derivatives and the inhibition of porphyrin synthesis was examined with ATP. The inhibition increases rather regularly with the increasing amounts of ATP. The most efficient concentration seems to be 3 mM/l. In either of the concentrations investigated the growth of micro-organism and the synthesis of bacteriochlorophyll were significantly modified (Table 3).

Table 2. Growth and Synthesis of Porphyrin and Bacteriochlorophyll in Mixture *Ia* of Lascelles. Effect of AMP, ADP and ATP (Incubation, 48 h)

Medium	Dry weight of organism (mg/ml.)	Porphyrin (μmM/ml.)	Bacteriochlorophyll (μmM/ml.)
Mixture *Ia* of Lascelles	2·66	21·7	3·22
Same mixture + AMP, 3 mM/l.	2·66	13·2	3·55
Same mixture + ADP, 3 mM/l.	2·76	3·9	3·97
Same mixture + ATP, 3 mM/l.	2·83	1·8	4·18

Table 3. Effect of ATP in Increasing Amounts on Growth and Synthesis of Porphyrin and Bacteriochlorophyll (Incubation, 48 h)

Medium	Dry weight of micro-organism (mg/ml.)	Porphyrin (μmM/ml.)	Bacteriochlorophyll (μmM/ml.)
Mixture *I* of Lascelles	1·2	39·3	1·75
Same mixture + ATP, 250 μM/l.	1·2	33·2	1·56
Same mixture + ATP, 500 μM/l.	1·3	22·1	1·61
Same mixture + ATP, 750 μM/l.	1·3	19·8	1·88
Same mixture + ATP, 1,000 μM/l.	1·3	17·0	2·21
Same mixture + ATP, 3,000 μM/l.	1·3	2·4	2·40

The inhibitory effect of the adenine derivatives seems to be located, as suggested by our earlier observations[4], to the first step of porphyrin formation, namely, to the synthesis of δ-aminolævulinic acid. In fact, no inhibition has been noted when these compounds are added to suspensions of *Rhodopseudomonas spheroides* in mixture *II*, containing δ-aminolævulinic acid as substrate (Table 4).

Table 4. Effect of AMP, ADP and ATP on Growth and Synthesis of PBG, Porphyrin and Bacteriochlorophyll in Mixture *II* containing 100 μg ALA per ml. (Incubation, 24 h)

Medium	Dry weight of organism (mg/ml.)	ALA unchanged (μmM/ml.)	PBG (μmM/ml.)	Porphyrin (μmM/ml.)	Bacteriochlorophyll (μmm/ml.)
Mixture *II* of Lascelles	0·5	603	3·1	0·49	0·61
Same mixture + AMP, 3 mM/l.	0·5	603	3·1	0·47	0·60
Same mixture + ADP, 3 mM/l.	0·5	617	3·5	0·50	0·59
Same mixture + ATP, 3 mM/l.	0·5	656	3·3	0·61	0·61

The inhibition of porphyrin synthesis by adenine, adenine nucleosides and nucleotides may represent a feed-back regulation. Δ-aminolævulinic acid is not only a precursor of porphyrins, but it participates also, by its fifth carbon atom, in the biosynthesis of purines, as was shown by Shemin *et al.*[8]. Thus it can be assumed that, according to the definition of the feed-back inhibition, the purine derivatives examined act as end-products on the first step of their formation, with the resulting decrease of biosynthesis of δ-aminolævulinic acid and porphyrins. In this respect, it was interesting to note that pyrimidine derivatives—as thymine, uracil or orotic acid—did not exert any inhibition on porphyrin biosynthesis by *Rhodopseudomonas spheroides* (Table 5).

Table 5. Effect of Tymine, Uracil and Orotic Acid on Growth and Synthesis of Porphyrin and Bacteriochlorophyll in Mixture *I* (Incubation, 48 h)

Medium	Dry weight of micro-organism (mg/ml.)	Porphyrin (μmM/ml.)	Bacteriochlorophyll (μmM/ml.)
Mixture *I* of Lascelles	1·5	24·9	2·44
Same mixture + thymine, 3 mM/l.	1·6	27·7	3·02
Same mixture + uracil, 3 mM/l.	1·6	25·2	2·34
Same mixture + orotic ac., 3 mM/l.	1·5	25·8	2·68

The observations recorded here confirm and complete our earlier findings showing the inhibitory effect of

adenine nucleosides and nucleotides on excess porphyrin formation. This inhibitory effect may constitute one of the physiological mechanisms regulating porphyrin biosynthesis.

Specificity of Pepsin and its Dependence on a Possible 'Hydrophobic Binding Site'

The specificity of pepsin has been extensively investigated, and the information obtained from work using synthetic di- or tri-peptides indicates that pepsin preferentially hydrolyses peptides which contain a tyrosine or phenylalanine residue[1,2]. However, Sanger, using the *A* and *B* chains of insulin, found that peptide linkages which did not involve tyrosine or phenylalanine were hydrolysed by pepsin[3,4]. Bovey and Yanari[5] recently reviewed the action of pepsin on synthetic peptides and proposed several general rules. It was pointed out, however, that these rules "do not necessarily apply to the peptic digestion of proteins and large polypeptides, which is often considerably more extensive than these rules would lead one to expect". In order to understand the action of pepsin on protein substrates, we have made a systematic examination of the sequence of amino-acid residues adjacent to the site of peptic hydrolysis in several proteins of known amino-acid sequences. In this communication, a concept is proposed which explains the specificity of pepsin for protein substrates in terms of a hypothetical 'hydrophobic binding site'.

Information on the site of hydrolysis of pepsin on insulin was obtained from the work of Sanger *et al.*[3,4], on α-corticotropin from Li[6] on ribonuclease from Hirs *et al.*[7], and on the α-chain of human hæmoglobin from Konigsberg and Hill[8]. A tabulation of the sequence of the first five amino-acids on either side of the site of cleavage by pepsin was made for these four proteins. An example of a part of the tabulation is shown in the following:

← To N-terminal					To C-terminal →				
CO5	CO4	CO3	CO2	CO1	NH1	NH2	NH3	NH4	NH5
Asp	Lys	Thr	Asp	Val	Lys	Ala	Ala	Tyr	
	Lys	Ala	Ala	Tyr	Gly	Lys	Val	Gly	Ala
Ala	His	Ala	Gly	Glu	Tyr	Gly	Ala	Glu	Ala

↖ Peptide linkages hydrolysed

If another site of hydrolysis was found before the fifth residue, the sequence was discontinued. The results of the hydrolysis of sixty-five bonds were tabulated, and the percentage of the total number of residues of each amino-acid found in a given position is shown in Table 1.

On the basis of the percentile distribution, the amino-acids were classified in three groups: (1) The first group (highly susceptible amino-acids) consists of, in the order of preference by pepsin, phenylalanine, leucine and tyrosine, all of which appear in relatively high frequencies in the CO1 and NH1 positions. Since these three amino-acids bind to all amino-acid residues in a random fashion, the high susceptibility of peptide linkages containing these three amino-acids must be due exclusively to their presence. (2) The second group (susceptible amino-acids), which includes glutamic acid (+glutamine), alanine, aspartic acid (+asparagine), methionine, valine, threonine, lysine, serine, and histidine, consists of those amino-acids which are susceptible to peptic hydrolysis but which are distributed rather evenly throughout the ten sequential positions. (One exception was observed for histidine at the CO4 position. However, its significance is uncertain.) (3) The third group includes glycine, isoleucine, proline, arginine and cysteic acid. None of them appears in the CO1 position and only three appear in the NH1 position (two with very low frequencies). This group is thus designated as non-susceptible amino-acids. An examination of nineteen peptide bonds involving phenylalanine, leucine, or tyrosine (members of the highly susceptible group) not affected by peptic hydrolysis revealed that in thirteen of these bonds the other amino-acid is one of the three amino-acids belonging to the third group: proline, arginine and cysteic acid. These three amino-acids should therefore be considered as 'anti-susceptible amino-acids'.

It seems clear from the foregoing information that the probability of a peptide bond being hydrolysed by pepsin depends mainly on the nature of the residues on the carbonyl side (CO1 position) of the peptide linkage, and, to a somewhat less degree, on the amino side of the linkage (NH1 position).

Since the side-chains of phenylalanine and leucine, two of the most highly susceptible amino-acids, consist of

Table 1. Frequency of Appearance of Amino-Acids at Ten Sequential Positions around the Hydrolysed Linkage*

Sequential positions	CO5	CO4	CO3	CO2	CO1	NH1	NH2	NH3	NH4	NH5
First group (highly susceptible):										
Phenylalanine	0	0	0	8 (0)	81	47	0	38 (0)	24 (12)	16 (0)
Leucine	0	0	5	14 (14)	59	33	25 (25)	35 (9)	14 (14)	29 (10)
Tyrosine	16 (0)	13 (0)	8 (0)	15 (8)	24	24	6 (6)	7 (7)	11 (11)	15 (15)
Second group (susceptible):										
Glutamic acid (+ Glu—NH_2)	10	15	18	34	28	28	31	21	13	18
Alanine	14	33	27	22	21	21	29	15	5	20
Aspartic acid (+Asp—NH_2)	9	7	24	23	16	22	18	0	6	24
Methionine	40	0	0	0	14	0	0	17	0	0
Valine	37	0	17	33	10	20	23	20	13	9
Threonine	28	0	33	6	10	15	17	6	0	13
Lysine	31	24	48	9	7	8	9	9	14	0
Serine	18	0	24	23	6	13	14	22	6	33
Histidine	16	77	0	29	6	12	14	21	34	15
Third group (non- and anti-susceptible):										
Glycine	17	64	38	15	0	6	6	0	22	15
Isoleucine	0	0	65	30	0	0	0	0	0	0
Proline	53	54	32	8	0	19	21	15	0	33
Arginine	0	0	12	11	0	0	0	0	0	24
Cysteic acid	37	15	17	0	0	7	7	48	0	17

* The data represent the percentage of an amino-acid residue appearing at a given position. The calculations were made according to the following formula: for example, leucine at position CO2 is calculated:

$$\%\ \text{of leucine at CO2} = \frac{\text{No. of leu found at CO2} \times \dfrac{\text{Total No. of tabulated peptide bonds hydrolysed}}{\text{Total No. of residues found at CO2}}}{\text{Total No. of leucine found in four proteins}} \times 100$$

The data in parentheses are the percentages of the residues after discounting those which are directly involved in the hydrolysis of other bonds.

only hydrocarbon groups, the affinity of pepsin toward these groups must be assumed to be apolar in nature. It is thus hypothesized that there exists a site on the pepsin molecule which binds the hydrocarbon side-chains of the amino-acid residues in the substrate through a hydrophobic bond as an essential step of enzymatic action. (For a recent review in the hydrophobic bond see ref. 9.) The following observations and discussion support the foregoing hypothesis.

A grouping of the amino-acids according to the nature of their side-chains is presented in Table 2. There exists an apparent correlation between the number of carbon atoms in the side-chains and the frequency of appearance at the CO1 position. The tendency for the less water-soluble residue to be more abundant in the susceptible positions supports the possibility of hydrophobic binding site between the enzyme and substrate. The standard free energy of formation of hydrophobic bonds between some isolated side-chains has been calculated by Némethy and Scheraga[9]. A correlation between free energy of formation of hydrophobic bonds and the frequencies of appearance of the amino-acids in group *A* (Table 2) is obtained only when it is assumed that the hydrophobic binding site of pepsin is phenylalanine. The striking low frequency of the amino-acids in group *B* seems to be due to steric effects, since the arrangement of the carbon skeleton in the side-chain of isoleucine and valine is basically different from those belonging to group *A*.

Table 2. CORRELATION OF THE NO. OF CARBON ATOM IN THE SIDE-CHAIN OF AMINO-ACIDS AND THE FREQUENCY OF THEIR APPEARANCE AT CO1 POSITION

Side-chains	Amino-acid	No. of carbon atoms in the side-chain	Standard free energy of formation† (kcal/mole)	Solubility in water* in mole fraction (No. × 10^4)	% of residues appeared at CO1
A Hydrocarbon, with all or part of benzyl group	Phe	7	−1·4	32	81
	Leu	4	−0·5	32	59
	Ala	1	−0·2	327	21
	Gly	0	—	566	0
B Hydrocarbon, not part of benzyl group	Ileu	7		56	0
	Val	3		135	10
C Contain oxygen	Tyr	7		0·7	24
	Glu (+Glu—NH_2)	3		54‡	28
	Asp (+Asp—NH_2)	2		34‡	16
	Thr	2		31	10
	Ser	1		86	6
D Contain nitrogen	His	4			6
	Lys	4			7
	Arg	4			0
E Others	Met	3		41	14
	Crys—SO_3H	2			0
	Pro	3		2,028	0

* Calculated from the data in Cohn and Edsall (ref. 10).
† Taken from Némethy and Scheraga (ref. 9), assuming that the side-chain of phenylalanine is the 'binding site' of pepsin.
‡ The solubility data for glutamine and asparagine are used, since the carboxylic group does not ionize below *p*H 2. It is thought that glutamine and asparagine would be more representative.

The presence of acidic or basic groups in the side-chains, known to hinder the formation of hydrophobic bonds, decreases the 'frequencies' of amino-acids in groups *C*, *D*, and *E*. The effect of the hydroxyl group is apparent when tyrosine is compared with phenylalanine, and serine to alanine. The lower susceptibility of the nitrogen-containing residues in group *D* could be attributed to the positive charge of nitrogen-containing groups at *p*H 2, the *p*H of peptic hydrolysis, whereas the carboxylic and hydroxyl groups do not ionize at that *p*H. The resistance of a cysteic acid residue seems also to be due to its highly acidic sulphonic group. In the case of proline, however, the low affinity could be explained by the difference in the bond angle in the back bone of the peptide linkages.

Although the proposed 'hydrophobic binding site' appears to determine the point of hydrolysis in protein substrates, it is unlikely that this 'site' participates in the mechanism of hydrolysis. The binding of the side-chain of the substrate to the hydrophobic site of the enzyme may be visualized as the first step in the enzyme action, which is followed by hydrolysis of the peptide bond through a yet unknown mechanism. The formation of new amino- and carboxylic-groups, however, could reduce the effectiveness of the hydrophobic binding of the side-chain to the 'site' and thus release the product from the enzyme.

It should be pointed out that in the present analysis the rate of hydrolysis of different peptide linkages is not considered. However, during the incubation of proteins with pepsin, if time is not allowed for completion of the hydrolysis, then the bonds hydrolysed would be those preferred by the enzyme. This appears to be the case in the hydrolysis of ribonuclease[7] by pepsin, since the resulting peptides are quite large. Insulin[3,4] did not present a problem, since in the work of Sanger[3,4] care was taken to distinguish the faster hydrolysed linkages from the slower ones. In α-cortico-tropin[6] and α-chain of human hæmoglobin[8], some of the more preferable peptide linkages still could be determined. If one finds in the hydrolysate a long peptide and several smaller peptides which apparently result from the further degradation of the long peptide by the enzyme, the peptide linkages cleaved at the terminals of this long peptide must be preferred by the enzyme over those at sites cleaved to give smaller peptides. Attempts were made to tabulate and analyse the result from only the more preferable peptide linkages. The conclusions drawn, however, are not significantly different from the analysis which utilizes all peptides cleaved.

It is possible that a 'hydrophobic binding site' may be present in other proteolytic enzymes. Chymotrypsin, for example, also prefers to attack a peptide linkage which contains an aromatic amino-acid. However, like pepsin, the hydrolytic action is not restricted to the bonds which contain an aromatic residue. Carboxypeptidase *A* and some cathepsins, which have affinity toward aromatic amino-acids, may also contain such sites.

Preparation of an Insulin *A* Chain Derivative with an Intact Intra-chain Disulphide Bond

THE insulin molecule contains three disulphide bonds according to Sanger's structure formula[1]. Two of these connect the peptide chains; the third forms an intra-chain linkage between residues 6 and 11 on the *A* chain. Various authors have shown that there are differences in the reactivities of the three disulphide bonds[2]. However, in the presence of concentrated solutions of urea or guanidine hydrochloride complete cleavage is observed as well by oxidative sulphitiolytic as by reductive procedures with thioglycolate or 2-mercaptoethanol[3]. The recombination of completely reduced insulin chains by re-oxidation with air gave only low yields in the experiments of several groups of investigators[4–6], in accordance with theoretical statistical calculations made by Kauzmann[7].

Table 1. Physical and Chemical Data of the Isolated Insulin Chain Derivatives

Abbreviations: *calc.*, calculated; *f*, found; *pol.*, polarographic determination of cystine; *col.*, determination of cystine by the method of Folin–Shinohara.

Recently, Cecil *et al.*[8] demonstrated by polarographic studies of the sulphitolytic disulphide cleavage, such as:

$$R.SS.R + SO_3^{--} \rightleftharpoons RS^- + R.SSO_3^-$$

a definite preferential cleavage of the two inter-chain disulphide bonds with sodium sulphite in aqueous solution at *p*H 7. They gave analytical evidence that the remaining intact SS bond is the 6–11 intra-chain ring of the *A* chain. We have been able to isolate in a preparative scale the *A* chain with the intact disulphide bond and to characterize the compound by cystine analysis using two independent methods, by elementary analysis, and by optical rotation (Table 1).

For the preferential selective cleavage of the two inter-chain disulphide bonds and the isolation of the *A* chain with the intact intra-chain SS ring crystalline zinc insulin (1 g) was treated at *p*H 7·2 and 35° C with a 250-fold excess of sodium sulphite. The reaction mixture was stirred mechanically for about 5 h while a stream of nitrogen was passed over the surface of the solution. After exhaustive dialysis in 'Visking' tubes 18/32 against 25 charges of distilled water at 5° C the *A* and *B* chain derivatives were precipitated with dilute hydrochloric acid at *p*H 4·8. The centrifuged solid mixture was redissolved in *p*H 1·9 buffer (50 ml.) containing 5 per cent acetic acid and 5 per cent formic acid and then passed through a 'Dowex 50—*X*2 column' (200–400 mesh, 2·2 cm × 14 cm), which had been equilibrated with the same buffer. The chromatogram was developed at room temperature with a flow rate of 25 ml./h and a volume of 5 ml. per fraction. The eluates were analysed by determination of the ultra-violet absorption at 278 mμ. Two peaks were obtained. The contents of the peak tubes (4–15 and 26–34) were lyophilized and the yields of *A* and *B* chain derivatives were 82 and 90 per cent respectively. The cystine content was determined by means of the polarographic Brdička reaction[9], and by the colorimetric method of Folin–Shinohara. The data presented in Table 1 demonstrate that the isolated *A* chain derivative is *A* chain 6,11-disulphide-7,20-*bis*-thiosulphate.

When this material was subjected to further treatment with sodium sulphite in the presence of 8 M urea the resulting reaction product was identical in electrophoretic behaviour with *A* chain tetrathiosulphate which we isolated in earlier investigations. We suggest that the *A* chain derivative with the intact intra-chain SS bond may be used with some more success in recombination studies. Hitherto, we obtained 4–7 per cent of original insulin activity on recombination of completely reduced insulin chains prepared by the oxidative sulphitolytic method.

We thank Prof. H. Zahn for advice and criticism, and for help with the preparation of the manuscript. We also thank the Bundeswirtschaftsministerium, Bonn (Forschungsvorhaben I 399), for a research grant.

Intestinal Degradation of Gamma-globulin in the Dog

Increased catabolism of plasma proteins by leakage into the gastrointestinal tract and subsequent digestion by the intestinal enzymes may play an important part in normal plasma protein degradation[1,2]. All classes of plasma proteins seem to leak into the gastrointestinal lumen, but only albumin has been examined quantitatively[3–5]. In the work summarized here a quantitative estimation of the transfer of plasma γ-globulin to intestinal lumen has been made and suggestive evidence is presented that the amount of γ-globulin catabolized in the intestine of the dog is determined mainly by the capillary permeability of γ-globulin.

γ-Globulin was isolated from the serum of normal dogs by column chromatography on diethylaminoethyl cellulose[6] and labelled with iodine-131 (ref. 7). The turnover and exchange rates of γ-globulin were calculated by the method of Matthews[8] after intravenous injection of labelled γ-globulin in seven dogs. In the same dogs, four to seven weeks later, following a new intravenous injection of iodine-131 labelled γ-globulin, the transfer of plasma γ-globulin to intestinal lumen was determined by measuring the transfer of protein-bound radioactivity to isolated segments of the small intestine. Three segments (30–50 cm each, corresponding to 8–18 per cent of

the total length of the small intestine) of the small intestine were isolated between tape ligatures, one orally, one anally and one about the middle. The segments were filled with 22·5 ml. saline containing soybean trypsin inhibitor (0·5 mg/ml.) through a thin 'Nelaton' catheter introduced through an enterostomy orally to the segment. The solution was aspirated after 10 min; protein-bound radioactivity was measured and by means of plasma radioactivity the intestinal clearance of γ-globulin (Cl_{int}/min) was calculated. The turnover rate of γ-globulin may be expressed as metabolic clearance per day[9] and indicates the volume of plasma containing the amount of γ-globulin catabolized per day (Cl_{met}/day). The fraction of total turnover of γ-globulin catabolized in the intestine may now be expressed by:

$$\frac{Cl\ /min}{Cl_{met}/min}$$

assuming that the intestinal clearance of the segment is representative for the whole of the small intestine.

Results of these experiments are presented in Table 1. Fractional turnover rate varied from 17 to 29 per cent (mean 22 per cent) of the plasma pool a day and the exchange rate to extravascular compartments from 26 to 58 per cent (mean 43 per cent) of the plasma pool a day. The metabolic clearance was from 38 to 111 μl. (mean 66 μl.) per min. The intestinal clearance varied from 6 to 43 μl./min (mean 24 μl./min) calculated for the whole of the small intestine, and no difference was found between the proximal, middle and distal sections; the intestinal clearance constituted 21–74 per cent (mean 38 per cent) of the metabolic clearance. In other words, these experiments indicate that about 40 per cent of the total amount of γ-globulin catabolized is broken down in the lumen of the intestinal tract. A significant correlation was found between exchange rate and the fraction of total γ-globulin turnover catabolized in the intestine ($r = 0{\cdot}84$; $0{\cdot}01 < P < 0{\cdot}02$) (Fig. 1). Since these two parameters are determined independently in two different experiments, this suggests that the intestinal exudation of γ-globulin found was not caused by the experimental procedure, because it is highly improbable that an artefact should be correlated to a physiological parameter. The exchange rate of γ-globulin, as determined by the method of Matthews[8], reflects the capillary permeability of γ-globulin. The correlation between exchange rate and intestinal degradation of γ-globulin, therefore, suggests that capillary permeability of γ-globulin is an important limiting factor in the passage of γ-globulin from plasma to intestinal lumen. This might indicate that the intestinal mucosa and epithelium are of minor importance as a barrier to intestinal exudation of γ-globulin and implies that altered capillary permeability and not changes in the intestinal epithelium should be in the cause of protein-losing gastroenteropathy, a disease of hitherto unknown ætiology.

A Low-temperature Emission Band from Dilute Solutions of Pure Chlorophyll a

PREVIOUSLY published fluorescence spectra of chlorophyll *a* in dilute ethyl ether solution show a major band with maximum at 668 mμ and a minor band with maximum at 723 mμ, at room temperature[1,2]; at 77° K in ether–isopentane–ethanol (EPA), chlorophyll also exhibits two emission bands, with maxima at about 684 and 735 mμ[3].

Dilute acetone solutions of crystalline chlorophyll *a*, prepared by us according to either the method of Jacobs, Vatter and Holt[4] or Anderson and Calvin[5], also yield emission spectra containing two major bands—with maxima at 668 and 725 mμ at 77° K (Fig. 1, curve I). However, on further purification, an additional band with

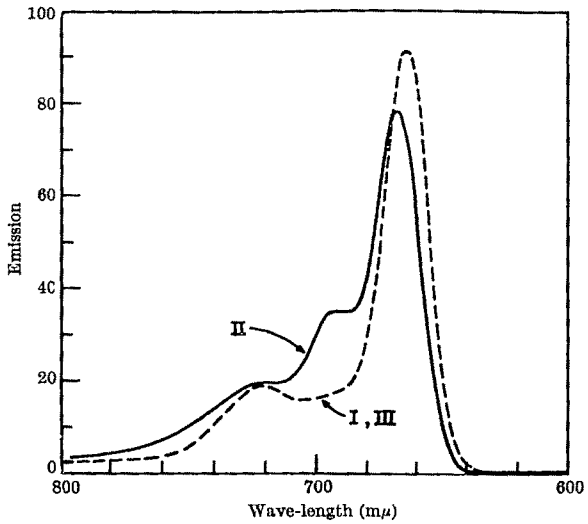

Fig. 1. Emission spectrum of a 10^{-5} M solution of chlorophyll *a* in acetone at 77° K; exciting wave-length 436 mμ. Curve I, emission spectrum of chlorophyll *a* before purification; curve II, emission spectrum of purified chlorophyll *a*; curve III, quencher added to sample shown in curve II (see text). The spectra have not been corrected for the spectral response of our Dumont 6911 photomultiplier tube. However, its response varies by only 10 per cent in the wave-length region shown

maximum at 698 mμ is observed in acetone at 77° K; in this solvent the two previously mentioned bands exhibit maxima at 671 and 725 mμ (curve II). No other emission band could be detected although measurements were made out to 1,100 mμ[6]. At room temperature the new band is not observable. The three-peaked emission spectrum characteristic of the purified chlorophyll *a* was found at 77° K, in dilute solutions of chlorophyll in acetone, ethanol, benzene, pyridine and ethyl ether. (The solvents were reagent grade, but were not further purified or dried.)

The purification technique which we used consisted of re-adsorbing the previously chromatographed chlorophyll on diatomaceous earth, washing it exhaustively with petroleum ether, and recrystallizing it in the fashion of Jacobs *et al.*[4]. Since the concentrated washings from 100 mg of chlorophyll *a*—which exhibit a pale yellow colour—yield an almost imperceptible residue on drying, the substance in question must be present in very low concentration. No appreciable change in the absorption spectrum or extinction coefficient of chlorophyll is observed after purification.

Adding the petroleum ether washings to the purified chlorophyll completely quenches the emission at 698 mμ (curve III); there appears to be a slight change in intensity of the emission maximum at 671 mμ (curves II and III). Nitrobenzene and *p*-phenylenediamine also quench the new band. The orange and yellow materials ordinarily extracted from plants do not quench the 698 mμ emission; included among those we tested were commercial preparations of β-carotene, α-carotene, and vitamin K, as well as xanthophylls and carotenes, which we extracted from spinach.

Since the naturally occurring quencher (which we obtained from our petroleum ether washings) is not readily removed from chlorophyll *a*, even after repeated chromatography, it is likely that it exists as a complex with chlorophyll. This contention is also supported by the fact that even in very minute amounts it will quench the 698-mμ emission. We are in the process of identifying this quencher, and have begun measurement of the lifetime of emission from the new band (698 mμ).

The possibility of some fluorescent material being introduced by the diatomaceous earth was eliminated by washing the earth with petroleum ether, extracting with ethyl ether and then examining the concentrated ethyl ether fraction for emission at 698 mμ at 77° K; no emission was observed.

Since the emission band at 698 mμ is readily quenched, the excited state giving rise to it may be effective in sensitizing photoreactions. Perhaps this emission band originates from a metastable state of chlorophyll such as postulated by Franck[7] in his theory of photosynthesis.

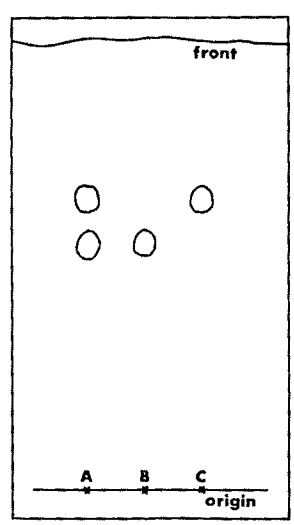
Resolution of a Racemic Pteridine during Paper Chromatography

When ethyl pyruvate and 4,5-diaminopyrimidine were refluxed in water, between *p*H 1 and 3, a solid of molecular weight about 320 was formed which was seen as two spots[1] after dissolution in 0·1 N sodium hydroxide and chromatography on a sheet of Whatman No. 1 paper in water at *p*H 5·5 or 8·5. The spots (Fig. 1*A*) had R_F values of 0·55 and 0·65 respectively and appeared identical when viewed in ultra-violet light. When eluted, and rechromatographed, each spot generated only one spot, which corresponded in R_F to the spot from which it was eluted (Fig. 1*B* and *C*).



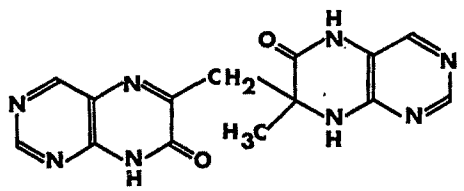


Fig. 1

When a larger quantity (50 mg) was chromatographed on a column of cellulose (diameter 4·7, and length 120 cm), two fractions were obtained which, after recrystallization from boiling water, were found to have the same four pK_a values and ultra-violet spectra as the material prior to chromatography. But whereas the original material was optically inactive, crystals from the faster-running fraction had the specific rotation $[\alpha]_{546}^{20} = +180° \pm 5°$, and those from the other fraction had $-180° \pm 5°$ (both measured at *p*H 9·1).

It was later found that the original racemate could also be made by refluxing 6-hydroxy-7-methylpteridine with 7-hydroxy-6-methylpteridine in water at *p*H 2·5. Further investigations, to be reported in detail elsewhere, showed that it was 6-(7,8-dihydro-6-hydroxy-7-methyl-

pteridin-7-yl)methyl-7-hydroxypteridine (I), formed by an acid-catalysed addition reaction of the two simpler pteridines. The molecule contains one asymmetric carbon atom.

(I)

Cellulose is an optically active substance and several authors[2] have reported that various DL-amino-acids (for example, tryptophan and histidine) are resolved in non-optically active solvents during chromatography on a sheet of paper. Resolution was demonstrated by showing that one of the two spots formed was identical with that given by the L-acid. But so far as we know, pairs of enantiomorphs have not previously been eluted from a paper sheet or a cellulose column, nor has the degree of resolution been demonstrated by measurements of optical rotation.

PHYSIOLOGY

Influence of 2,4-Dinitrophenol on Anion Transport by an Intestinal *in vitro* Preparation

RECENT observations carried out on isolated and *in vitro* perfused preparations of the small intestine of the rat have confirmed that sodium is actively transported through the intestinal wall from the mucosal to the serosal side[1-5]. For such a transport glucose must be present in the mucosal solution; some metabolic inhibitors, 2,4-dinitrophenol (DNP) or monoiodoacetate, when added to the perfusion liquid, inhibit this transport[2,6]. The chloride ions cross the intestinal wall together with cations and for the transport of these ions, too, an active mechanism has been assumed[3,7].

The behaviour of the anion transport when DNP is added to the preparation seems also to support the view of an active chloride transport. Preliminary results[8] were obtained by perfusing the intestine on both sides with an apparatus similar to that used by Smyth and Taylor[6]. The results reported here were obtained on jejunum everted sacs of albino male rats (Wistar strain) according to the technique of Wilson and Wiseman[9]. The intestinal preparations were incubated for 1·5 h at a temperature of 28° C. Krebs–Henseleit solution[10] aerated by a mixture of 95 per cent oxygen and 5 per cent carbon dioxide was used as incubating fluid. The sodium concentration in the serosal fluid at the end of the experiment was determined by means of an 'Optica *CF4*' flame spectrophotometer ($\lambda = 589$ mμ). The calculation of the net sodium transport across the intestinal epithelium was made on the assumption that the concentration of sodium in the serosal liquid and in 20 per cent of the fresh tissue are the same. Lactic acid was determined both in the mucosal and serosal fluids according to the method of Barker and Summerson[11]. In order to calculate the amount of lactic acid present in the serosal side, an equal distribution in the serosal fluid and in 80 per cent of the fresh tissue was assumed. The total carbon dioxide in the mucosal fluid at the beginning (25 mM/l.) and at the end of the experiment was determined according to Van Slyke and Neill[12]. In order to calculate the amount of bicarbonate transported into the mucosal epithelium, the amount of carbon dioxide set free by acidification due to the presence of lactic acid in the mucosal fluid was subtracted from the total amount of carbon dioxide which disappeared in the mucosal fluid. The volume of the transported solution across the intestinal wall was determined by weighing the intestinal sac before and at the end of the incubation period.

The results (Table 1) clearly show that in the control experiments a fraction of the total amount of transported sodium ions was accompanied by lactate and bicarbonate ions, the remainder being presumably accompanied by chloride ions. The ratio sodium transported/bicarbonate entered into the mucosal epithelium is 1·8, in agreement with the results given by Gilman and Koelle[1,2]. In the experiments carried out after DNP poisoning the sodium net transport was markedly reduced and the sodium ions seemed to cross the wall accompanied only by lactate. In this case, the ratio sodium transported/bicarbonate entered into the mucosa or the ratio sodium transfer/lactic acid present in the mucosal fluid is close to 1.

As the lactic acid concentrations in the mucosal as well as in the serosal side do not vary in the DNP experiments, we may suppose that even in the mucosal epithelium the lactate concentration does not vary after DNP poisoning. If this assumption is correct, a chemical interference of DNP must be admitted in order to explain the complete suppression of the transport of chloride after DNP poisoning; therefore, an independent active mechanism seems to be implicated in the chloride transport through the intestinal mucosa.

The gradient, which occurs between the serosal and mucosal lactic acid concentrations, does not change in the

Table 1. Everted small intestine of albino male rats (Wistar strain) weighing about 250 g. Jejunum portions starting 20 cm from pylorus and weighing 0·5–1 g were chosen. In each everted sac 0·3 ml. of the Krebs solution without glucose was initially introduced and the sac was then incubated for 1·5 h in the same Krebs solution containing 13·9 mM/l. of glucose. Initial quantity of incubating solution, 50 ml. Temperature of incubation, 28 ° C. Oxygenation with a mixture of oxygen, 95 per cent, and carbon dioxide, 5 per cent. Comparison of Fœtal Pulmonary Fluid with Fœtal Plasma and Amniotic Fluid

The fluid in fœtal lungs has been considered to be aspirated amniotic fluid[1], an ultra-filtrate of plasma or an exudate from the lungs or bronchial system[2]. Scattered and casual reports have appeared in the literature to the effect that, after delivery of a fœtus by Caesarean section, fluid continues to be formed in the lungs on such a scale as to suggest that the lungs may be an important source of amniotic fluid[3]. However, except for one instance[4], no observations on the nature of the fœtal pulmonary fluid have been reported. It has been possible to collect tracheobronchial fluid during the course of experiments on mature fœtal lambs for comparison with plasma and amniotic fluid in this laboratory. The experiments were performed for a different purpose and the observations reported here are consequently limited in scope.

Mature lamb fœtuses were delivered by Caesarean section from ewes anæsthetized with chloralose (30 mg/kg initially). A saline-filled rubber bag was placed over the head of the fœtus and the trachea was surgically exposed. After the trachea was carefully opened, a polyethylene catheter was passed into the trachea to the carina or slightly beyond and the fluid contained therein collected in a dry syringe. The trachea was then cannulated and the chest was opened on the left side. At no time during the procedure did the animal gasp or make respiratory movements. During the following surgical procedure, the left main bronchus was ligated and a small polyethylene catheter was placed in the left bronchial system through a small puncture in the left main bronchus below the ligature. Fluid from the lung was allowed to drain freely into a graduated cylinder, the end of the catheter being placed at the level of the lung or 2–5 cm below the lung. The collection period ranged from 15 min to 1 h. The initial sample of tracheo-bronchial fluid and the subsequent bronchial collection were analysed for osmolarity by the method of freezing point depression, as were samples of amniotic fluid obtained before delivery by needle puncture of the amniotic sac. When it was possible, samples of blood were obtained from the fœtus at the end of the experiment and plasma osmolarity was also determined. The results are presented in Table 1.

It is evident that the osmolarity of the fluid contained in the fœtal lungs at delivery is intermediate between that of amniotic fluid and that of plasma and is certainly not unadulterated amniotic fluid. Following delivery, while still in the fœtal state, fluid continues to be evolved from the lungs, occasionally at an astonishingly high rate. This fluid is identical in osmolarity with plasma and it would appear, therefore, to be simply a transudate from the pulmonary vascular system, its displacement from the blood stream being a natural consequence of the greater blood pressure which exists in the fœtal pulmonary circulation.

Table 1. Osmolarity of Fœtal Plasma, Amniotic Fluid and Tracheal Fluid collected immediately after Delivery (1) and Bronchial Fluid collected after Ligation of Left Main Bronchus (2)

Fœtus No.	Plasma (mosm/l.)	Amniotic fluid (mosm/l.)	Tracheal (1) Bronchial (2) fluid (mosm/l.)	Rate of flow (ml./h/kg)
1364 *A*	339	279	308 (1) 331 (2)	0·85
1344	332	296	315 (1) 334 (2)	6·25
1350	—	258	315 (1) 331 (2)	2·39
1364 *B*	324	276	327 (1) 320 (2)	1·43
1338 *A*	—	302	340 (1)	
1322	—	300	356 (1)	
Average	332	285	327 (1) 329 (2)	

The observations presented here support the view that the lungs may contribute to the formation of amniotic fluid but not as osmotically identical fluid. This finding does not corroborate the observations of Setnikar, Agostoni and Tagglietti[4], who found the osmolarity of the tracheal fluid to be the same as that of the amniotic fluid in goat fœtuses. It may be that their experimental conditions were such as to promote fœtal respiratory movements and aspiration of amniotic fluid just prior to delivery.

Although the initial osmolarity of tracheobronchial fluid is hypotonic to plasma, it would be inappropriate to refer to it as 'amniotic fluid', whether aspirated or secreted, because in every instance the tracheal fluid was hypertonic to the amniotic fluid. The most reasonable inference would be that the pulmonary fluid *in utero* is a filtrate of plasma which is diluted by the diffusive movement of water from the amniotic fluid through the open upper airway or by the occasional bulk movement of amniotic fluid brought about by respiratory movements.

I thank Drs. G. S. Dawes and J. C. Mott for their co-operation in obtaining samples for this work and Semiconductor Thermoelements (Frigistor), Ltd., for lending me the osmometer used in the analyses.

HÆMATOLOGY

Appearance of Slow α_2-Globulin after Interference with the Liver

Darcy[1,2] first identified a protein in the sera of rats bearing large neoplasms or tight abdominal bandages which was absent in the sera of healthy, non-pregnant adults.

Beaton *et al.*[3] showed the protein to have the mobility of an α_2-globulin in paper electrophoresis but, because it migrates more slowly than β-globulin in vertical starch-gel electrophoresis, it is commonly referred to as slow α_2-globulin (SA_2G).

Beaton *et al.*[4,5], and Heim[6,7] have shown SA_2G to appear in the sera of fœtal, neonatal, young, pregnant and lactating rats, and have confirmed its appearance in rats bearing large neoplasms. SA_2G did not appear in the sera of normal adult or sub-adult, healthy, non-pregnant rats nor in rats treated with œstrogen, progesterone, growth hormone, chorionic gonadotropin, ACTH[8] or thyroxin[8].

Since most of the conditions leading to the appearance of SA_2G in the sera of rats seem to be related to either developmental or neoplastic growth situations, we attempted to determine, in the light of this apparent correlation, whether or not SA_2G would appear during liver regeneration following partial hepatectomy or damage induced by carbon tetrachloride administration.

Sera were obtained, and vertical starch gel electrophoresis was performed by the method of Smithies[9] with minor modifications, as previously described[7]. Partial hepatectomy was performed by the method of Higgins and Anderson[10] with two modifications: (1) a transverse incision rather than a longitudinal one was used; (2) only the central bifurcated lobe, equal to about 26 per cent of the total liver weight, was removed. Despite the removal of a much smaller proportion of the liver, the patterns of regain in weight of liver and changes in rates of mitotic activity were essentially the same as those observed by Higgins and Anderson[10], with the peak of regenerative activity falling between the first and third days after operation.

Sham hepatectomies were performed in the same manner as the partial hepatectomies, including manipulations of the viscera, but without either ligating or excising any portion of the liver.

Carbon tetrachloride was administered intraperitoneally as 40 per cent solution in mineral oil[11], using a dose of 0·834 ml./kg body-weight. The liver showed both gross and histological damage. Contrary to the observations of Leduc[11] on the livers of mice, that damage due to carbon tetrachloride administration is primarily centrolobular, we found the damage in rats to be rather general. The histologically observed repair processes were parallel in time to the regenerative activity observed after partial hepatectomy.

Table 1. Occurrence of Slow α_2-Globulin after Partial Hepatectomy and Carbon Tetrachloride Injection

Treatment	Presence*	No. of animals in each category at indicated No. of days after treatment						
		0	0·5	1	2	4	6	9
Partial hepatectomy	−	—	0	0	0	0	0	9
	+	—	2	0	0	0	4	1
	+ +	—	4	6	8	5	0	0
Sham hepatectomy	−	—	—	—	9	11	—	—
	+	—	—	—	3	1	—	—
	+ +	—	—	—	1†	0	—	—
Carbon tetrachloride injection	−	—	3	3	3	0	5	2
	+	—	4	1	0	0	1	0
	+ +	—	0	3	7	2	0	0
Mineral oil injection	−	—	—	—	9	5	—	—
	+	—	—	—	0	0	—	—
	+ +	—	—	—	0	0	—	—
Untreated control rats	−	26						
	+	2						
	+ +	0						

* −, No slow α_2-globulin demonstrable; +, some slow α_2-globulin demonstrable; + +, much slow α_2-globulin demonstrable.
† Signs of wound infection.

The results obtained are shown in Table 1. SA_2G was observed most frequently and in the highest apparent concentration in those rats in which the greatest regenerative or repair activity was going on following either partial hepatectomy or carbon tetrachloride injection. Untreated control animals, animals injected with mineral oil only and animals subjected to sham hepatectomies generally were negative in respect to the appearance of SA_2G in their sera. As already observed by Beaton *et al.*[5], occasionally a supposedly normal animal will show some SA_2G, but in such cases the animals are usually sick and exhibit signs of diarrhœa.

From these results it would appear that SA_2G can be demonstrated in the sera of rats during regenerative growth and during repair of tissue damage. The occasional failure to observe SA_2G after carbon tetrachloride administration may be due to the possibly indirect mechanism which has been postulated for the activity of carbon tetrachloride in respect to the liver[12]. We are at present investigating whether or not SA_2G appears in the sera after excision of those organs the removal of which involves either only compensatory hyperplasia without regeneration or only wound closure without either of the foregoing.

PHARMACOLOGY

Enhanced Suppression of the Secondary Immune Response by Combination of 6-Mercaptopurine 'Duazomycin A'

The demonstration that 6-mercaptopurine (6-MP) is capable of inhibiting the immune response[1,2] has aroused much interest and optimism concerning the therapeutic possibilities for organ transplantation and 'auto-immune' diseases. Extension of these studies has shown that immunological tolerance can be obtained by administration of 6-MP during the primary exposure to an antigen[3]. Although initial attempts to modify the secondary response to the antigen were unsuccessful[4], a quantitative rather than qualitative effect seems to have been responsible, since proper timing and vigorous treatment with both antigen and drug will achieve complete suppression of specific antibody production in previously immunized animals[5,6].

The precise mechanism of action of 6-MP is not yet known. Present evidence indicates that, after enzymatic conversion to the ribonucleotide, the analogue interferes with the biosynthesis and inter-conversion of purine nucleotides, but does not replace to a significant degree the normal components of nucleic acids or coenzymes[7]. The biosynthesis *de novo* of normal purine derivatives also can be inhibited effectively by certain reactive diazo-compounds[8,9], including *O*-diazoacetyl-L-serine (azaserine) and 6-diazo-5-oxo-L-norleucine (DON). Marked potentiation is observed when combinations of these agents and 6-thiopurines are used in the chemotherapy of experimental neoplasms[8,9]. Early clinical studies, however, disclosed little or no therapeutic advantage of these combinations in patients with neoplastic disease[10,11]; but such trials utilized the oral route of administration, now recognized to be unsatisfactory, since the diazo-compounds are inactivated by acid-hydrolysis[7]. More recent investigations, utilizing a new glutamine antagonist, 'Duazomycin *A*' (DZM) (*N*-acetyl-DON), in combination with 6-thioguanine (TG), by the intravenous route have shown much more favourable initial results[12].

The work recorded here was conducted to investigate the effects of the combination of DZM and 6-MP on the suppression of the secondary immune response in rabbits previously immunized with a non-living antigen, diphtheria toxoid. The results indicate that DZM, without significant increase in toxicity, potentiates appreciably the ability of 6-MP to block antibody production (Table 1).

Thirty albino rabbits were used in two separate experiments. The animals were inoculated intradermally with 176 *Lf* units of diphtheria toxoid in volumes of 0·1 ml. into the shaved plantar surface of the foot-pad. (Formol toxoid No. 32929-361 was kindly supplied by Mr. W. S. Hammond of Lederle Laboratories.) Using hæmagglutination of sensitized tannic acid-treated sheep erythrocytes as the indicator, a primary antibody response was obtained in every animal. The procedure followed was that described by Boyden[13], as adapted by Stavitsky to the diphtheria toxin–antitoxin system[14,15]. A second identical injection of diphtheria toxoid was given 4–6 weeks later. Drug therapy was initiated on the same day of the challenging injection of antigen and was continued for 6 days, using the dosage schedules shown in Table 1. Sera were titrated blindly and 1+ agglutination[14], which was found to be the most reproducible, was used as the end-point. Solutions of DZM were obtained in sterile ampoules containing 2 per cent disodium phosphate buffer. (We thank Dr. Theodore Medrek of Chas. Pfizer and Co., Inc., for supplies of 'Duazomycin *A*' (DZM).) 6-MP, Burroughs Wellcome and Co. (lot 42596), was dissolved daily in a solution of sodium hydroxide (1 M), diluted to desired concentration with sterile saline, and adjusted to *p*H 9 by titration with dilute hydrochloric acid. Sera wore obtained on days 2, 4 and 6 and antibody titres (Table 1) were determined by the procedure already described.

Table 1. Effect of 6-Mercaptopurine (6-MP) and 'Duazomycin *A*' (DZM) on the Secondary Immune Response to Diphtheria Toxoid

* Animal died on day 4 subsequent to traumatic cardiac puncture.

This demonstration of enhanced suppression of antibody response to non-living antigen has prompted investigations with homotransplantation, which, although still incomplete, suggest similar results. These findings will be of particular interest in view of reports indicating prolonged survival of renal homotransplants in dogs treated with related agents[16]. Further investigations of glutamine antagonists in combination with purine analogues are clearly indicated, in order to determine their effects on delayed hypersensitivity, γ-globulin-levels and 'auto-immune' disease in experimental animals and man.

The mechanism of action of antimetabolites in suppressing the immune response is not yet clearly understood. Because most agents that possess this property also inhibit cellular proliferation, it has been postulated that this effect is mediated through selective destruction of small clones of antibody-producing cells, particularly if these have been stimulated into mitotic activity by the administration of the appropriate antigen. It is of interest, therefore, that the drug combination used has a well-documented ability to inhibit cellular proliferation and was selected on rational biochemical concepts for its ability to produce a concurrent multi-site blockade of purine biosynthesis. Furthermore, because DZM is characterized by minimal bone marrow toxicity and 6-MP usually has no severe gastrointestinal effects, it is hoped that the anti-immune effects in man will not be accompanied by increased toxicity. In patients with advanced neoplastic disease receiving treatment with combinations of 6-MP, TG or the respective 5-imidazolyl derivatives, and DZM similar immunological studies have been initiated in order to evaluate the effects of these drugs on the immune response in man.

Effect of Benzquinamide on Blood Pressure

Two substances of the benzoquinolizine group have different effects on depletion of brain catecholamines. While tetrabenazine (intravenous) produces a decrease in the brain amine concentration, benzquinamide (intravenous, supplied by Pfizer Argentina, S.A.) produces a rise in the serotonin- and noradrenaline-level (5 HT: 0·65 γ/g; control: 0·57 and noradrenaline: 0·63 γ/g; control: 0·39).

Benzquinamide is the 2-acetoxy-3-diethylcarbamyl-9,10-dimethoxy-1,2,3,4,6,7,hexahydro-II bH-benzo-a-quinolizine.

Per os, it has a potent tranquillizing and anti-emetic activity, producing little or no sedation. When given intravenously, a significant increase in arterial blood pressure has been observed.

This effect on blood pressure was found while examining its anti-emetic activity during anæsthesia with barbiturate or halothane[1].

This drug has a very weak antihistamine, antiserotonin and anti-cholinergic action.

It was decided to examine its hypertensive experimental effect in rabbits. Ten animals were used, 5 in the control group and 5 under anæsthesia with barbiturates (pentothal). Blood pressure was recorded with an intra-arterial catheter in the popliteral artery, using a mercury manometer with a graphic register[2].

In the control group, an increase in the systemic blood pressure was obtained after the intravenous injection of benzquinamide. It was accompanied by trembling, convulsions, myosis, venous congestion and cyanosis.

The results are summarized in Table 1.

Table 1

Exp. No.	Control blood pressure (mm Hg)	Benzquinamide dosage (mg/kg)	After benzquinamide blood pressure (mm Hg)
1	40	20	70
4	60	20	68
7	45	10	53
8	50	13	78
10	40	20	72

In the animals submitted to barbiturate anæsthesia the following results (as shown in Table 2) were obtained.

Table 2

Exp. No.	Control Blood pressure (mm Hg) Initial	Control Blood pressure (mm Hg) After pentothal	Benzquinamide (mg/kg)	After benzquinamide blood pressure (mm Hg)
5	48	40	20	46
6	50	40	20	50
9	42	38	20	52
12	55	50	20	60
14	42	36	20	52

In all animals an increase in blood pressure was evident. Between 20 and 30 min after the injection of benzquinamide, the blood pressure returned to its initial values. It seems that those animals submitted to anæsthesia have a minor pressure response than the controls. It must be pointed out that no vasoconstriction was observed (as happens with noradrenaline injection)[3]. On the contrary, a marked peripheral vasodilatation was noted.

In a previous paper we examined the blood pressure response to intravenous noradrenaline[2] in animals pretreated with an amino oxidase inhibitor: iproniazid[4,5]. In this case the response seems to be higher than in the controls.

A Fatal Case of Poisoning with Amitriptyline

NEW psychopharmacological drugs bring relief to many patients. However, their misuse can result in misadventures which may even be fatal. Several reports[1] already document this fact, despite the wide margin of safety these drugs have. This note reports a fatal episode involving amitriptyline, another new drug in the fast growing list.

In the previous 3-year period a 25-year-old man (A. M.) unsuccessfully attempted suicide twice. He was placed under the care of a psychiatrist. His therapy included many different drugs. In the last 6 months only amitriptyline was prescribed. At 6 a.m. one morning A. M. was found dead beside his bed. He was last heard from at 3 a.m. of the same day when he had spoken with a friend. On the table in the same room one tablet ('Laroxyl®', 25 mg) was found. A bottle, now empty, was known to have contained about 50–100 tablets. A. M. was taken to the Institute of Legal Medicine in Basle, where a post-mortem examination was performed. Macroscopic and microscopic pathological examinations revealed no anatomical cause of death. There were no abnormalities except for a full stomach containing 295 gm of undigested food and some white particulate matter.

Chemical analyses were then made. Routine tests indicated opiates, phenothiazine derivates, meprobamate, barbiturates and glutethimide were not present. However, the white particulate matter in the stomach was chemically separated from all other material and was found to be amitriptyline.

'Amitriptyline' (Trade marks: 'Elavil', 'Laroxyl', 'Tryptizol', 'Tryptanol', 'Saroten', 'Sarotex', 'Horizon')

Two different methods were used for the isolation and detection of the drug. These are presented so that others faced with a similar problem may benefit from this experience.

One method was a modified Stas–Otto procedure. A portion of the sample is homogenized with water and ethanol. This mixture is heated under a reflux condenser, for 60 min. The mixture is then cooled, the solid matter separated by filtration and the clear filtrate vacuum distilled to remove the ethanol. The residual aqueous solution is then extracted with ether. These extracts were evaporated to dryness. An aliquot part of the residue was placed on a thin layer chromatogram (silica gel *G*) and run for 30 min in a methanol/acetone/triethanolamine (1 : 1 : 0·03) solvent. The resulting chromatogram was sprayed first with Dragendorff's reagent and then with potassium iodoplatinate. An orange spot at the same R_F as known amitriptyline indicated the unknown was probably this drug. The iodoplatinate spray revealed a second slower running spot which was probably a metabolite of amitriptyline, since it only appeared in the extracts from blood, liver, kidney, urine and not in the stomach content extract.

Table 1

	Stomach	Blood	Liver	Kidney	Brain	Urine
Direct extraction	> 20 mg/ 100g	—	—	—	—	—
Direct extraction after hydrolysis	not done	0·04 mg/ 100 g	1·5 mg/ 100 g	0·5 mg/ 100 g	not done	not done
Extraction after Stas–Otto	100 mg/ 100 g	0·04 mg/ 100 g	—	1·0 mg/ 100 g	5 mg/ 100 g	1·3 mg/ 100 g

The second method was a direct chloroform extraction of the samples using 10 volumes of chloroform to each volume of sample. The extractions were made on homogenized samples of several different tissues, blood, and stomach contents. One series was extracted directly. A second series was first hydrolysed at 100° C for 30 min with 50 per cent hydrochloric acid. Both series were made alkaline by the addition of solid potassium hydroxide. 10–15 ml. aliquots of each sample were successively extracted with 100 ml. chloroform. Each aliquot was discarded and the next added to the same chloroform until the entire sample was extracted. The chloroform was then washed with 20 ml. of 0·5 N sodium hydroxide. The sodium hydroxide was discarded and the chloroform extracted with 5 ml. of 1 N sulphuric acid. The ultraviolet absorption characteristics of this acid extract were recorded. Then the sulphuric acid solution was made alkaline and extracted with ether. The ether was dried over anhydrous sodium sulphate and then evaporated to dryness. The residue was dissolved in methanol and thin layer chromatography, as previously described, was performed.

Both these techniques were applied to samples of blood, stomach content, liver, kidney, brain and urine. The semi-quantitative data recorded in Table 1 are based on the size and density of the thin layer spots compared with standards prepared in an identical manner.

It is interesting to note that when the direct-extraction procedure was applied to unhydrolysed samples, no significant amounts of drug were detected. This is com-

parable with similar recorded data for phenothiazine derivatives[2], imipramine[3] and some tranquillizers[4].

Whether the amount of drug detected in A. M. was enough to cause his death may be debatable. Albeit low, they are comparable with values reported for similar drugs. A better judgement could be made if comparable data were available from living human patients who are being treated with this drug. However, until this kind of data are available from those responsible for the use of this drug, the results in Table 1 may be presumed to be compatible with death, especially in absence of an anatomical cause of death.

PATHOLOGY

An Organ Culture System for the Examination of Tumour Invasion

For investigations of many of the processes involved in the invasion of normal tissues by malignant cells it is desirable to have an *in vitro* system where the interacting normal and tumour tissues maintain the 3-dimensional tissue structure which they possess *in vivo*. Wolff[1] has used with considerable success a system involving the organ culture of combinations of various tumours with embryonic chick mesonephros, where extensive growth of the tumours accompanies the invasion of the embryonic normal tissue. We wished to develop a system using adult or new-born mammalian organs where the fully differentiated architecture of the normal tissues could be maintained in contact with tumour tissue, with a minimum of cell division.

We have made use of a modification of Trowell's[2] technique, in which we placed small fragments of tissue on a rayon strip laid on a stainless steel grid, the underside of which was in contact with the medium, usually Eagle's HeLa + 10 per cent calf serum. The cultures were maintained in an atmosphere of 95 per cent oxygen + 5 per cent carbon dioxide at 37° for seven days. The normal and tumour tissues, cut to a suitable shape and size, were laid side by side, on top of each other, or overlapping. The normal tissues most commonly used were kidney, liver, lung and skin of young mice, and the mouse tumours were the Harding–Passey melanoma, Sarcoma 180 and a solid transplantable myeloma. The melanoma was used most frequently since the melanin within the cells permitted the identification of individual tumour cells.

Fusion of the normal and tumour tissues occurred within a few days, and examination of sections after seven days in culture revealed the infiltration of melanoma cells into the adjacent organized normal tissues, see Figs. 1 and 2. The infiltration was not in the form of solid columns of tumour cells, but by single or small groups of cells, which were embedded in and surrounded by apparently healthy normal tissue, in which the histological structure was well preserved. No traces of the path of infiltration could be detected. Individual tumour cells

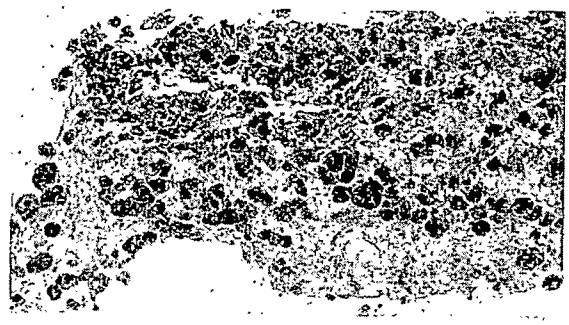

Fig. 1. Section of a 7-day culture of rat liver showing invading pigmented mouse melanoma cells

Section 2. Section of 7-day culture of rat kidney with infiltrating mouse melanoma cells (arrowed)

had penetrated within the normal tissues for distances of up to 400μ in 7 days.

In many sections there were definite indications that the tumour cells had been unable to penetrate connective tissue which was orientated parallel to the tumour–normal tissue interface, an observation previously recorded by Leighton, using sponge matrix cultures[3]. If resistance to infiltration by tumour cells is dependent solely on the relative strengths and stabilities of the intercellular adhesions of normal tissue cells, one would expect that compact tissues such as liver would resist infiltration more successfully than connective tissue. It seems more probable from our work and that of others that the failure of melanoma cells to penetrate the parallel orientated normal connective tissue is due more to the operation of the principle of contact guidance[4] than to the physical barrier which the connective tissue represents. Contact guidance would direct the movements of tumour cells parallel to the overall orientation of the connective tissue. Therefore, tangentially orientated connective tissue would present a barrier, and radially orientated connective tissue would provide a highway for invasion.

The organ culture technique used in this work provides a three-dimensional system for examining the roles of contact guidance, contact inhibition[5,6], nutrition, hormones and other factors on the process of tumour cell infiltration into normal tissues which have maintained, to a large extent, their architectural integrity. The infrequency of mitosis makes possible such investigations in the absence of extensive growth, and the system is in many ways complementary to that of Wolff[1], where considerable growth of the tumour accompanies invasion of the embryonic chick mesonephros.

Many pathologists[7,8] have emphasized the role of pressure, developed by increase in tumour volume, in determining the onset and route of invasion along the

paths of least mechanical resistance. The progressive infiltration of individual tumour cells which has been observed in the organ culture systems cannot be attributed to the development of pressures, as growth of the tumour under the conditions of culture is very small and, moreover, individual tumour cells cannot exert pressures of the type suggested. The mechanism of invasion based on loss of contact inhibition by malignant cells seems to offer the most consistent explanation of these observations. If these cultures can be maintained for increasing lengths of time without increase in tumour cell mass it should be possible to observe progressive stages of invasion dependent mainly on the motilities and contact behaviour of the tumour and normal cells.

One of us (G. C. E.) thanks Dr. I. Lasnitzki for advice in the organ culture technique. This investigation was supported by grants to the Chester Beatty Research Institute (Institute of Cancer Research: Royal Cancer Hospital) from the Medical Research Council, the British Empire Cancer Campaign, the Anna Fuller Fund, and the National Cancer Institute of the National Institutes of Health, U.S. Public Health Service.

Production of Ultra-structural Glomerular Lesions resembling those of Toxæmia of Pregnancy by Thromboplastin Infusion in Rabbits

The characteristic histological abnormalities of toxæmia of pregnancy (pre-eclampsia) are found in glomeruli and consist mainly of endothelial swelling[1]. Electron microscopic studies of renal biopsies have confirmed that the main change is marked swelling of endothelial and intercapillary cells, and have shown in addition the frequent occurrence of dark, granular material deposited between the swollen endothelial cells or along the basement membranes[2,3].

The hypothesis was advanced that these glomerular changes are the result of a prolonged and very slow state of intravascular clotting, as discussed elsewhere[4]. Evidence for this hypothesis was provided by the results of experiments in which 14 rabbits were perfused with various amounts of tissue thromboplastin ('Difco'). The duration of perfusion varied from 2 h up to about 30 h, and the animals were killed between 1 and 12 h after completion of the perfusion. Ten of these rabbits showed histological abnormalities, consisting of various degrees of endothelial swelling, polymorphonuclear infiltration and fibrin deposits. Glomeruli of 6 of these rabbits were examined by electron microscopy and showed the following features.

In the most severe reactions, large amounts of fibrin were found in the capillary lumens, often entrapped with platelet clumps; platelets appeared to play an autocatalytic part in formation of fibrin, since fibrin threads were often seen to be formed in direct contact with platelets undergoing viscous metamorphosis. Fibrin was also present within intercapillary cells in the same location where injected colloidal materials are known to be deposited; this further substantiates the phagocytic properties of these cells[5], and shows that the fibrin

Fig. 1. Part of a rabbit glomerulus showing swelling of endothelial and intercapillary cells which reduces the capillary lumen

present in lumen can be removed as any colloidal material. The phagocytosis of fibrin was not limited to intercapillary cells; endothelial cells showed progressive swelling and were frequently observed in the process of phagocytosing fibrin present in the lumen. Following its ingestion by endothelial cells, fibrin was observed in vacuoles, undergoing progressive degradation until it was no longer identifiable. Deposits of dark, granular material, similar to those found in toxæmic glomeruli, were frequently observed in the capillary lumens, or sometimes within the intercapillary or endothelial cells.

The following lines of evidence indicate that this material was derived from fibrinogen: (*a*) In some capillary loops materials exhibiting all the transitional aspects between fibrillar fibrin and these deposits were observed. (*b*) The same material was found in experiments in which intravascular clotting was induced by other means, namely, injections of thrombin or of Liquoid[6]. When epsilon-amino-caproic-acid, an inhibitor of fibrinolysis activators, was injected before the induction of intravascular coagulation, this resulted in a marked increase in the amounts of this material within glomeruli[6]. The term fibrinoid, which has sometimes been applied to this material, seems to be appropriate since it appears to be the result of the accumulation of some fibrinogen derivatives in a stage of polymerization different from that of fully polymerized fibrin. It may represent intermediate products, either formed in the lysis of fibrin, or in the conversion of fibrinogen into fibrin. It is known that in slow states of intravascular clotting, circulating fibrin precursors are present in the absence of fully polymerized fibrin[7]. In several glomeruli, the presence of marked intercapillary and endothelial swelling and the deposits of this fibrinoid material, between the swollen cells or along the basement membrane, gave a picture indistinguishable from that observed in toxæmia.

In 2 rabbits, endothelial and intercapillary swelling was observed in the absence of any detectable fibrin formation or fibrinoid deposition (Fig. 1). The swelling started with the formation of blebs of the cellular membrane which protruded into the lumen, the so-called endothelial ballons, and progressed in some loops to complete occlusion of the capillary. The swollen cells often contained numerous vacuoles and vesicles, indicating phagocytic activity.

That all these changes result from fibrin formation and not of thromboplastin itself has been shown in experiments in which intravascular clotting was induced by thrombin and 'Liquoid', and which will be more extensively

described elsewhere[6]. Fibrin and fibrin precursors appear to behave in the circulation like colloidal material, since it has been demonstrated that they are phagocytosed by the reticulo-endothelial system[9]; the observations recorded here provide evidence that derivatives of fibrinogen behave like colloidal materials in that they are arrested in glomeruli and phagocytosed by the intercapillary and endothelial cells[9]. The existence of circulating fibrin or fibrinogen derivatives appears to be responsible for the cell swelling and deposits of dark fibrinoid material, which are the essential changes observed in toxæmia of pregnancy. The cell swelling, which was sometimes observed even in the absence of detectable fibrin formation, also appears to result from the phagocytosis of fibrinogen derivatives. That a mechanism of very slow intravascular clotting, perhaps initiated by the entrance in the maternal circulation of placental thromboplastin, can be responsible for the renal lesions of toxæmia, is substantiated by the recent demonstration by immunofluorescence of large amounts of fibrinogen derivatives in toxæmic glomeruli[4].

RADIOBIOLOGY

Determination of Carbon-14 in Plant Material by Wafer Counting

A simple method for quantitatively estimating carbon-14 in plant material (for example, carbon-14 tagged herbicides, as in our own case) is to press the material into wafers and to count these directly with a Geiger or proportional counter.

Since any wafer of plant material will almost certainly be at infinite thickness for carbon-14, the count obtained is directly proportional to the specific activity of the sample. If relative measurements only are required these data are sufficient. A quantitative measure of the radioactivity present in a wafer can be obtained from the infinite thickness equation:

$$I_\infty = \frac{sA}{\mu} \text{ (ref. 1)}$$

where I_∞ is relative measured activity at infinite thickness, corrected for background and coincidence loss (c/m); s is relative specific activity of the sample (c/m/mg); A is area of wafer exposed to the sensitive region of the counter (cm²); μ is absorption coefficient for carbon-14 β-particles in the material in question (cm²/mg).

Conversion to absolute units then requires knowledge of the counter efficiency and of the value of μ for the material in question. This information may be difficult to obtain.

A less theoretical method of converting the c/m observed from the wafer to an absolute quantitative measure of the weight of herbicide present is by use of a calibration curve. This is constructed by adding different known weights of the radioactive herbicide to known amounts of the plant material. Wafers are then made and counted in the same counting system as the harvested samples.

This communication reports a comparison of these two absolute quantitization methods of wafer counting for cotton-seed kernels. Also, an attempt was made to determine the absorption coefficient and the self-absorption curve of carbon-14 in cottonseed kernels.

A nuclear measurements *PC-3A* windowless-gas-flow proportional counter was used to count all wafers; the self-absorption curve was determined with a Nuclear Chicago *D-47* Geiger tube with a micromil window (0·150 mg/cm²). All counts were corrected for background; coincidence loss was never significant. In general, at least 2,000 counts were accumulated for each sample, giving an error at the 95 per cent level of 6 per cent; wafers were counted on both sides.

The relative specific activities of the radioactive herbicides were determined from a dilution series in absolute ethanol. Duplicate aliquots of the dilutions were pipetted into 1-in. diameter nickel planchets and dried under an infra-red lamp.

Wafers for the calibration curve were made by placing 1·5 g samples of cotton-seed kernels (hulls removed, oil not extracted), ground to pass a 60-mesh screen, in the steel cylinder (2·90 cm inside diameter) of a wafer-making press. Then a known weight (± 1 per cent) of the radioactive herbicide, dissolved in absolute ethanol, was pipetted into the ground kernels in the press and thoroughly mixed in by hand. The volume of fluid added was kept to 0·10 ml. or less to avoid excessive alteration of the consistency of the kernels. The wafer was pressed out with a minimum of force to avoid loss of the oil. The wafers were weighed to an accuracy of ± 0·1 mg after counting.

Counter-efficiency was determined by counting a disk containing carbon-14, of known absolute radioactivity, using the same geometry as the wafers.

The self-absorption curve was made by weighing out various amounts of ground cotton-seed kernels (with an accuracy of ± 0·1 mg) and suspending them in a few ml. of absolute ethanol and then thoroughly grinding in a Potter homogenizer. Then 2,4-dichlorophenoxyacetic acid-2-carbon-14 (2,4-D-2-carbon-14) of known radioactivity was added to the ethanolic suspension and thoroughly mixed in. The suspension was carefully transferred to a 1·25-in. diameter aluminium planchet and the ethanol evaporated off under an infra-red lamp; care was taken to see that the material was uniformly distributed over the planchet. Samples of 2,4-D-2-carbon-14 in ethanol were dried, counted and left for periods of more than 1 h under the lamp and then recounted. No change in count-rate was found. I_0 (the activity in the absence of any self-absorption) was determined by plating 2,4-D-2-carbon-14 without the addition of kernels.

Determination of μ. If a known amount of carbon-14 is added to a known weight of kernels and the resulting wafer counted, μ can be calculated in the following two ways. The first method involves no knowledge of the counter-efficiency, but it is necessary to measure the relative specific activity of the herbicide by a dilution series in a suitable solvent and then use this value to calculate s. Provided that the dilution series planchets and wafers are counted in the same machine and with similar geometry, there is no need to correct for machine efficiency. The second method requires the use of the counter-efficiency in the calculation, the specific activity given by the manufacturer (or any other absolute measure) being used to calculate s, and I_∞ being converted to an absolute value from the counter-efficiency.

The value of μ was determined from 24 wafers, containing 2,4-D-2-carbon-14 of two specific activities and pentachlorophenol-1-carbon-14 (PCP-1-carbon-14) of one specific activity. With a counter-efficiency of 45 per cent,

which was that calculated by use of the carbon-14 standard, μ was 0·256, and ranged from 0·204 to 0·316. It was unlikely that the counter efficiency was outside the range 40–50 per cent. If the efficiency was 40 per cent the 0·256 value of μ would become 0·227, if 50 per cent, 0·283. The value of μ obtained without bringing the machine efficiency into the calculations was 0·285, with a range from 0·222 to 0·361. The overall mean value using results from both methods of calculation was 0·270.

Comparison of the infinite thickness equation method of quantitization with the calibration curve method of quantitization. Two calibration curves were made, one for 2,4-D-2-carbon-14 and one for PCP-1-carbon-14. In each case, as was expected, a linear relation was found between the weight of radioactive herbicide added to the wafer and the observed c/m (corrected for background). Consequently, a factor could be derived from the curves to convert the observed corrected c/m to parts per million of herbicide. A comparison of the two methods is shown in Table 1. Results were calculated from the infinite thickness equation in the following way. Using the symbols as at the beginning:

$$s = \frac{I_\infty \times \mu}{A}$$

Converting to absolute values, using a machine efficiency of 45 per cent:

$$s = \frac{I_\infty \times \mu \times 100}{A \times 45}$$

From the absolute value of s thus obtained, the herbicide concentration, in parts per million, can be obtained by dividing s by the specific activity of the herbicide, as given by the manufacturer, and then multiplying the result by one million.

Table 1. Comparison of Methods for Calculation of Weight of Herbicide in Cotton-seed Kernels from Measurement of the Amount of Radioactivity present in a Wafer

^{14}C containing compound in wafer	Relative weight of herbicide calculated * from: (1) Calibration curve	(2) Infinite thickness equation, where μ = 0·23	0·24	0·25	0·26	0·27	0·28	0·29	0·30
2,4-D-2-^{14}C	1·00	0·91	0·95	0·99	1·03	1·07	1·11	1·15	1·19
PCP-1-^{14}C	1·00	0·84	0·88	0·92	0·95	0·99	1·03	1·07	1·10

* For full details, see text.

Table 1 shows that if μ is 0·27, which was the mean value found, the weight of herbicide is 107 per cent of the value obtained from a calibration curve for 2,4-D-2-carbon-14, and 99 per cent for PCP-1-carbon-14; if the value of μ for cotton-seed was the same as that usually taken for barium carbonate (0·29) the corresponding figures would be 115 and 107 per cent.

These results indicate that the correct value for μ for cotton-seed kernels is not very far from 0·29. On the basis of these studies, the authors believe that the most accurate way to calculate residue results from measurements of radioactivity at infinite thickness is to use a calibration curve of the type described.

Self-absorption curve. The curve obtained is shown in Fig. 1. All points are a mean of duplicate determinations. The self-absorption curve for barium carbonate (taken from ref. 1 and not determined on our counter) is shown for comparison. The similarity between the two curves indicates that the self-absorption properties of barium carbonate and cotton-seed kernels are similar, though it is known[2] that the shape of the self-absorption curve will vary with the counter used to construct it.

In summary, the value of the absorption coefficient of carbon-14 in cotton-seed kernels was estimated using measurements made at infinite thickness. A self-absorption curve for carbon-14 in kernels was also constructed. Results indicated that the usually accepted value of the coefficient (0·29) is approximately correct. If an absolute quantitative measurement of the amount of carbon-14 present in a wafer of pressed plant material is required, it is probably more accurate to use a calibration curve (in which known weights of the radioactive compound are added to non-radioactive plant material, the resultant wafers being assayed for radioactivity in the same counting system as the actual sample wafers) than to use the equation describing the behaviour of radiation at infinite thickness.

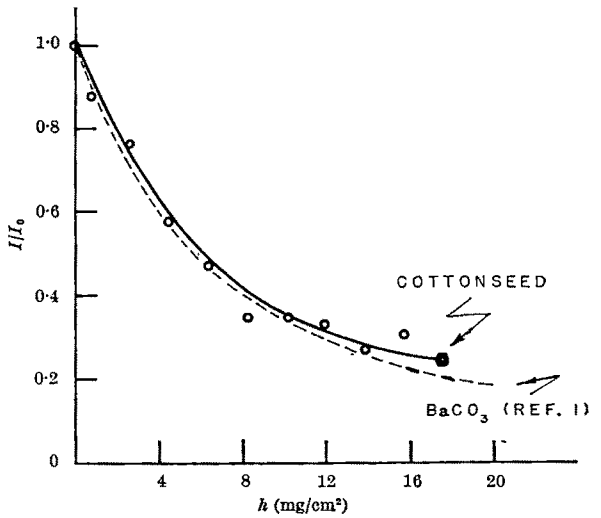

Fig. 1. Self-absorption curve for ^{14}C in cotton-seed kernels. I, Relative measured activity at less than infinite thickness, corrected for background and coincidence loss; I_0, relative activity present in the absence of self-absorption, corrected for background and coincidence loss

Influence of Calcium Phosphate on the Absorption of Radioactive Strontium

It has been found, in experiments which will be reported more fully elsewhere, that rats which are fasted before and after the intragastric administration of a solution containing strontium-85 absorb about three times as much of the strontium as rats with free access to the stock diet. It has also been found that when the stock diet is restored immediately after the administration of strontium-85 to fasted rats, the fraction of the dose absorbed is no greater than for fed rats. This effect is due mainly to one component of the diet, namely bone-meal. Calcium hydrogen phosphate mixed with cellulose and moistened with a solution of sucrose also reduces absorption when given to fasted rats after the strontium has been administered (Table 1).

Table 1. Effect of allowing rats to eat food containing 10 per cent bone-meal or cellulose containing 10 per cent $CaHPO_4.2H_2O$ on the absorption of ^{85}Sr administered intragastrically to them in the fasted condition

Treatment	Percentage dose absorbed
Fasted before and after dose	21
Stock diet* containing 10 per cent bone-meal fed after dose	5
Cellulose containing 10 per cent $CaHPO_4.2H_2O$ fed after dose	3

* Supplied by North Eastern Agricultural Co-operative Society, Ltd., Aberdeen.

To determine the period during which a protective effect could be obtained, the stock diet, containing 10 per

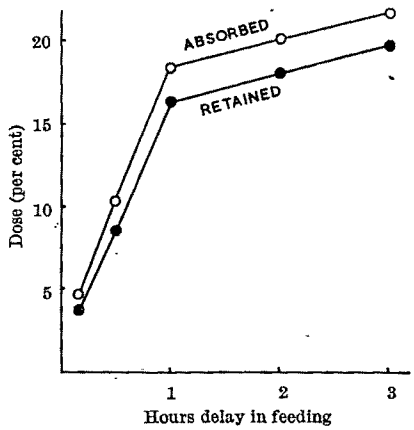

Fig. 1. Influence of food (containing 10 per cent bone-meal) consumed at different times after the intragastric administration of strontium-85 to fasted rats, on the absorption and retention of the strontium after 24 h. Each point is the mean value for 4 rats

cent bone-meal, was restored to fasted rats at various intervals after the administration of strontium-85. The animals each ate between 5 and 8 g of food. Twenty-four hours after receiving the strontium, the rats were killed and the gastrointestinal tract was removed intact. The strontium-85 was assayed in the residual carcass, urine, gut and fæces. Fig. 1 shows that the reduction in absorption (strontium-85 in carcass + urine) and retention (strontium-85 in carcass) after 24 h was greatest for rats which ate within a few minutes of receiving the dose. Absorption increased at further intervals until, at one hour, ingestion of the diet had little influence on the proportion of the dose absorbed. This is in accord with other data on the relationship between absorption and time from administration of strontium.

Macdonald, Spain, Ezmirlian and Rounds[1] found that tricalcium phosphate ($Ca_3(PO_4)_2$) reduced the absorption of strontium-90 when it was given at the same time as the strontium. The present data, however, show that a reduction in absorption may be achieved even if the calcium phosphate is eaten after the radioactive strontium is ingested. Consequently it would seem that calcium phosphate might prove a useful, safe means of reducing absorption after the accidental ingestion of radioactive strontium by man. Experiments are at present in hand to verify this.

Nuclear Factors involved in the Radiation-induced Depression of DNA Synthesis of Deoxyribonucleic Acid

In experiments described in a previous communication[1], it was found that nuclei isolated from regenerating liver of rats given 800 r. whole body irradiation incorporated less tritiated thymidine when assayed in a DNA-synthesizing system[2] at various times after irradiation than did non-irradiated controls. Somewhat similar results had been obtained by Van Lancker[3], who postulated that the finding might result from direct damage to the DNA template by irradiation. On the other hand, Nygaard[4] has suggested that these findings might result from loss of sodium and potassium from the nucleus due to irradiation damage to the nuclear membrane, such as has been demonstrated by Creasey[5] in the irradiated spleen.

In order to determine the site of radiation damage in the nucleus, experiments have been carried out using nucleoprotein fractions and DNA extracted from nuclei as a source of primer DNA in a DNA-synthesizing system. Nuclei uncontaminated with whole cells or cell debris were isolated in 0·44 M sucrose adjusted to *p*H 5·8 by the addition of citric acid[7]. The nuclei were then extracted in 0·14 M sodium chloride, leaving a residue which is designated DNA-histone consisting of DNA, histone, a non-basic protein which will be referred to as residual protein and some insoluble RNA. This residue was extracted in 0·2 N hydrochloric acid removing the acid-soluble histone, yielding the second fraction termed DNA-residual protein. These two preparations were dissolved in water at *p*H 8 and used as the source of primer DNA in the system previously described[1]. In all experiments, the source of DNA-synthesizing enzyme used was the supernatant from non-irradiated regenerating rat liver homogenates centrifuged at 35,000*g* for 1 h. In each experiment, the amount of DNA in each tube was adjusted to the same level.

Results from various preparations from liver 24 h after irradiation and 48 h after partial hepatectomy are shown in Table 1. In the first group of values obtained by using nuclei as primer, incorporation of tritiated thymidine is lower in the irradiated samples by a factor of roughly three compared with the controls. The second group of values is for DNA-histone; here again, incorporation into irradiated samples is less than into non-irradiated. In the third group, the DNA-residual protein is used as primer and here again incorporation into irradiated preparations is less than that into non-irradiated controls. In all cases, incorporation into the control preparation exceeds that into the irradiated preparation. Lastly, there are the values obtained with purified DNA extracted by the method of Dounce[6] from regenerating liver of irradiated and non-irradiated rats. Here there is little difference in the incorporation of tritiated thymidine into irradiated and non-irradiated preparations.

Table 1

Preparation	Exp. No.	Specific activity (c.p.m./mg DNA) Control	Irradiated	Ratio Irradiated/Control
Nuclei	1	23,545	7,894	0·334
	2	3,216	1,121	0·349
	3	5,047	1,630	0·323
DNA-histone	4	996	535	0·538
	5	53,150	17,990	0·337
	6	29,749	7,489	0·257
DNA-residual protein	7	6,690	1,780	0·266
	8	360	193	0·540
	9	1,894	662	0·350
DNA	10	2,232	2,008	0·90
	11	3,627	4,567	1·26
	12	6,078	8,082	1·33

Assays were performed with regenerating liver 48 h after partial hepatectomy and 24 h after 800 r. 250 kVp X-rays.

These results have a number of implications. First, the observed decrease in thymidine incorporation by the irradiated primer is clearly not related to changes in the nuclear membrane, which breaks down when the nucleoprotein is dispersed in water. Moreover, the suggestion that losses of sodium and potassium from the nucleus are involved is excluded on the basis of these results. Secondly, the nuclear components extractable in 0·14 M sodium chloride, namely, nuclear globulin and some soluble RNA, do not appear to be involved in reducing the ability of irradiated nucleoprotein to incorporate thymidine. Thirdly, the histone component of nucleoprotein, although it may play a part, is certainly not the sole factor involved in promoting the radiation lesion. The fact that the radiation-induced reduction in the ability of DNA to incorporate tritiated thymidine disappears when the DNA is freed of residual protein suggests strongly that the X-ray induced lesion which produces this effect resides in this nucleoprotein complex.

It has been observed in this laboratory that, following irradiation, the ratio of protein to DNA in the nucleus is altered. These changes may be involved in producing the results described here and are at present under investigation.

Utilization of Radiosulphate by Higher Plant Tissues

THERE is now considerable information concerning the pathway by which sulphate is incorporated into the amino-acids in micro-organisms[1]. In contrast, very little is known about the route for incorporation of sulphate into the amino-acids of higher plants or of the interconversions of these sulphur-containing amino-acids[2].

In the work recorded here, a variety of higher plant materials were examined for the incorporation of radiosulphate into the amino-acid fraction. In particular, the leaves, hypocotyls and cotyledons of radish seedlings were found to show a rapid incorporation of radiosulphate into the amino-acids. Similar patterns of incorporation were found when using cell-free extracts of these tissues supplied with adenosine triphosphate.

In the experiment shown in Table 1, 10-day-old radish seedlings were severed at soil-level and the hypocotyls placed in the buffered radiosulphate solutions as indicated. Samples of the seedlings were placed in the dark and in the light as shown and the uptake and incorporation of radiosulphate into the amino-acids were followed over periods up to 1 h.

At the end of the experimental periods, the seedlings were killed in boiling 80 per cent ethanol, and following homogenization, were extracted using dilute ethanol solutions and water[3]. Sulphate was removed from the soluble fraction by passing through 'Rexyn' columns in the hydrogen form and by ion exchange paper chromatography. The amino-acid fraction, eluted from the 'Rexyn' columns using 2 N ammonium hydroxide, was separated by two-dimensional paper chromatography[3]. The radioactive areas, ascertained by autoradiography, were eluted and the radioactivity assayed using a 'Mylar' window continuous gas flow Geiger–Müller tube. The counts were corrected for background and half-life decay.

It is evident from Table 1 that the uptake of radiosulphate was not appreciably affected by illuminating the seedlings. The rate of accumulation of sulphur-35 by the tissues was approximately linear over the 60 min experimental period. Activity was detected in the amino-acids and in material soluble in anhydrous ether. The latter fraction would presumably contain mustard oils which are abundant in plants related to the radish[4].

After 15 min of sulphate uptake in light or darkness, radioactivity was detected in the cysteine–cysteic acid area on the chromatograms. After 30 min, taurine-^{35}S was present in both treatments and methionine was labelled in the illuminated tissues. With increase in the experimental period to 1 h, the radioactivity in taurine decreased in the light but further increased in the seedlings in the dark. Furthermore, after 1 h, methionine sulphone-^{35}S was present in the tissues, the radioactivity in this compound being greater under conditions of illumination. The results are therefore in agreement with an earlier report[5], where excised mung bean leaves produced cysteine and methionine when infiltrated with radiosulphate.

Table 1. UPTAKE AND INCORPORATION OF RADIOSULPHATE BY EXCISED RADISH SEEDLINGS IN LIGHT AND DARK (EXPRESSED AS COUNTS/MIN)

Fraction	Light*			Dark†		
	15 min	30 min	60 min	15 min	30 min	60 min
Total ^{35}S taken up	115,500	234,000	402,500	106,000	183,000	390,000
Ether solubles	—	550	1,850	—	1,000	900
Amino-acid fraction, cysteic acid and cysteine	360	640	680	1,740	1,920	2,360
Taurine	—	3,240	1,920	—	600	2,100
Methionine	—	200	1,000	—	—	500
Methionine sulphone	—	—	1,450	—	—	400

5 μc. of carrier-free $^{35}SO_4$ in 0·02 M *tris* buffer *p*H 7·4 was fed through the hypocotyls of 0·75-g samples of seedlings.
* Illuminated with 500 ft.-candles in moving air at 25° C.
† Incubated in still air at 25° C.

Similar results were obtained when radiosulphate solutions were fed to slices of radish cotyledons, slices of young radish leaves and intact radish leaves. Tomato and *Coleus* leaves readily produced cysteine-^{35}S from radiosulphate, but methionine-^{35}S was not detected even after a 3-h experimental period.

Cell-free extracts of radish leaves prepared in 0·5 M sucrose, 0·02 M magnesium chloride and 0·025 M *tris* buffer at *p*H 7·4, containing chloroplasts and mitochondria, incorporated $^{35}SO_4$ into the amino-acid fraction.

This incorporation was not markedly stimulated by additions of TPN or by a system producing reduced TPN. Additions of ATP (1 micromole), however, caused a five-fold increase in the sulphur-35 content of the amino-acid fraction as compared to the extracts where cofactor additions were not made. More detailed experiments on sulphate metabolism *in vivo* and *in vitro* by the tissues are now in progress.

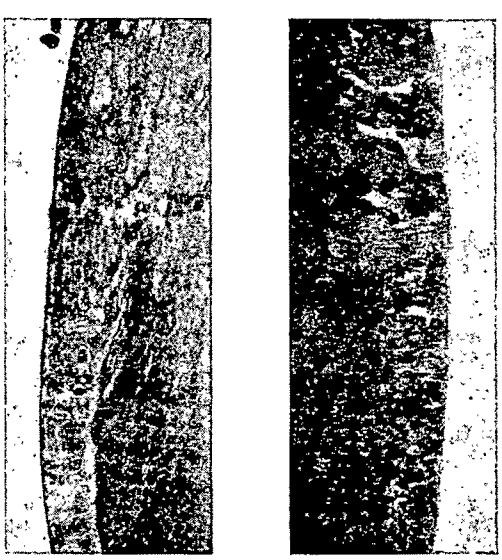
BIOLOGY

Two Components in the Development of Ray Cataract in Frogs

RECENTLY it has been shown in our laboratory that any intra-ocular operation on irradiated tadpoles seemed to result in the development of a ray cataract[1]. Later on, the same results were obtained in adult frogs and mice as well, in which an accelerated development of the aforementioned disease was also brought about by a fine pricking of the irradiated lens[2–4]. At the same time, judging by long-term observations on irradiated tadpoles and frogs, even a very heavy irradiation without subsequent operative intervention affects neither the transparency nor the structure of lenses. The experiments described here suggested to us that a direct relation existed between the degree of irradiation of the eye prior to operation and completeness of the opacity of the lens. Therefore, the question arose as to which doses of ionizing radiation—extreme, minimal, and maximal, combined with operative interference—provoked an accelerated development of the ray cataract.

a *b*

Fig. 1. Eye of a frog irradiated with 15,000 r. 1·5 h after pricking the lens a partial drawing of the lens epithelium to the anterior pole (*a*) can be seen, but no histological changes characteristic of the ray cataract can be found in a lens rendered completely opaque (*b*). (× *c.* 7·5 and × *c.* 15)



To answer this question, experiments were performed on frogs (*Rana temporaria*), which, like some other lower vertebrates, are distinguished by high resistance to ionizing radiations.

Two days after irradiation of the heads of these animals in a roentgen apparatus (RUD 100 kV/20 m.amp) the centre of one of the lenses was pricked, this time to a depth of no more than $\frac{1}{6}$–$\frac{1}{5}$ of its diameter. The control experiments showed that such a surface prick did not cause an unirradiated lens to become opaque. In all, 62 main and 33 control experiments were carried out.

Regular vital observations on the eyes of all the animals were carried out with the use of a slit lamp. Apart from this, many eyes were histologically examined.

It turned out eventually that the minimal irradiation dose which resulted in the development of a slight ray cataract after pricking was that of 500 r., the maximal being 12,000–15,000 r. The maximal dose was that which produced extremely rapid and strong opacity of the lenses. In the majority of cases this process occurred during 0·5–2·0 h.

After irradiation with the maximal dose and after pricking, a portion of the lens epithelium was drawn to the anterior pole of the lens (Fig. 1). A characteristic cross-shaped figure sometimes appeared in this region thereafter, which was connected to the formation of two crossing cracks running to the depth of the pricking performed. One of them appeared at the site of the anterior, vertical suture of the lens, the other at the site of its horizontal plane.

a *b*

Fig. 2. 1–2 h after pricking of a lens treated with the same heavy dose small vacuoles appear in the transitory zone (*a*), while aggregations of some substance appear in the posterior cortex (*b*). No migration of the cells of the transitory zone and no formation of the pseudoepithelium are found (× 200)

Histological examination of this material, fixed 0·5, 1·5 and 2 h after the operation, revealed the separation of some lens fibres, appearance of several small vacuoles in the transitory zone of the lens and multiple aggregations of some substance in their posterior cortex (Fig. 2). This substance stained similarly to pycnotic nuclei, but, when judged by special histochemical reactions, it was related neither to DNA nor to RNA.

The majority of the nuclei in the ganglion layer and many nuclei in the inner granular layer of the retina were conspicuously pycnotized. This was in good agreement with our previous investigations, which had shown a formative relation between normally functioning, mainly ganglion retinal cells and continuous histogenetic processes in the lens of tadpoles and frogs[5–7]. It may be possible that the ray cataracts in our animals were also formed as a result of a disturbance of the formative equilibrium between the retina and the lens.

Particular attention should be directed to the fact that, after the maximal irradiation and the pricking, no distortion of histogenetic processes characteristic of the ray cataract could be found in the lens rendered opaque—the distortion which many authors regarded as the cause of the opacity of the injured lens. In this case no balloon cells were found in the transitory zone, nor their migration to the posterior pole, and no formation of the pseudoepithelium was related to this latter process. The realization of these cellular processes requires a certain time which is lacking on the extremely rapid development of the provoked cataractal changes. In some cases, when the experimental animals were fixed in 3–5 days after the operation on parts of their eyes, one could see the beginning of pseudoepithelial formation.

Therefore, due to our acute experiments performed on the animals resistant to ionizing radiation, we succeeded in obtaining ray cataracts determined by only physicochemical disturbances in the lenses irradiated, while during the trivial development of the ray cataract in mammals and human beings, the physicochemical component of this disease found by us remained unnoticed, being manifested simultaneously with, and being closely related to, the well-expressed morphological, or better, pathohistological component.

Mode of Action of Selective Fungistatic Effect of Streptomycin

In the search for selective media for the isolation of *Phytophthora* and *Pythium* species from soil and infected plant tissue, relatively few results have appeared in the literature concerning the fungistatic effect of streptomycin. Eckert and Tsao[1] demonstrated that streptomycin inhibited the *in vitro* growth of *Phytophthora* species. Of five *Pythium* species investigated, *P. arrhenomanes*, *P. graminicolum* and *P. mamillatum* were inhibited by less than 100 p.p.m. streptomycin[2]. A number of investi-

gations have described the ineffectiveness of streptomycin against fungi, including some Oomycetes[4–7].

In this communication results of the fungistatic effect and possible mode of action of streptomycin against two representative Oomycete species are presented.

The *in vitro* fungistatic effect of streptomycin on *Phytophthora infestans* was studied with the agar plate dilution method in the concentration range of 25–200 p.p.m. Diameters of the colonies measured after incubation for 20 days at 15° C are presented in Table 1. Streptomycin at 25 p.p.m. strongly inhibited the growth of *Phytophthora*, whereas a concentration of 200 p.p.m. caused nearly complete inhibition.

Streptomycin also inhibited the *in vitro* growth of an unidentified *Pythium* species isolated from diseased bean roots. The degree of inhibition was estimated by measuring dry weight of mycelia grown in nutrient solutions which contained varying amounts of streptomycin. The dry weight of *Pythium* mycelia developed in the presence of 50 p.p.m. streptomycin was about 50 per cent less than that of the control. 500 p.p.m. streptomycin completely inhibited the growth of the fungus (Table 2).

Concentrations of streptomycin as high as 400 p.p.m. were not fungistatic to species of *Actinomucor*, *Cunninghamella*, *Rhizopus*, *Botrytis*, *Verticillium*, *Aspergillus*, *Trichothecium*, *Fusarium*, *Rhizoctonia*, *Aureobasidium* species and some yeasts.

It is notable that the streptomycin-sensitive Oomycete species have cellulose-containing cell walls, whereas the streptomycin-resistant Eumycetes have chitinous cell walls. It was decided, therefore, to test the hypothesis that variations in streptomycin absorption by the hyphæ of these two fungal groups was responsible for their differences in streptomycin sensitivity.

Table 1. *In vitro* FUNGISTATIC EFFECT OF STREPTOMYCIN ON *Phytophthora infestans*

Streptomycin concentrations (p.p.m.)	Colony diameters (mm)
200	9
100	13
50	22
25	30
0	100

Table 2. *In vitro* FUNGISTATIC EFFECT OF STREPTOMYCIN ON *Pythium* SP.

Streptomycin concentrations (p.p.m.)	Dry weights of mycelia (mg)
500	0
250	44
100	56
50	72
0	133

Table 3. STREPTOMYCIN UPTAKE OF MYCELIA OF VARIOUS FUNGI

Exp. No.	Streptomycin content (μg/g dry weight)				
	Pythium sp.	*Actinomucor repens*	*Cunninghamella echinulata*	*Rhizopus nigricans*	*Monilia sitophila*
1	620	2·5	—	—	—
2	237	0	39	53	—
3	137	2	41	29	14
4	213	24·5	36	65	—

Investigations were conducted on the absorption of streptomycin by hyphæ of *Pythium* sp. and a number of streptomycin insensitive, chitinous fungi: *Actinomucor repens*, *Cunninghamella echinulata*, *Rhizopus nigricans* and *Monilia sitophila*. The fungi were grown on Czapek's agar containing 2 per cent malt extract and 150 p.p.m. streptomycin. The controls contained no antibiotic. After incubation for 6 days the mycelia were carefully removed from the surface of the agar, dried and homogenized in a volume of tap-water 20 times their dry weight. The streptomycin content of mycelial homogenates of *Pythium* sp. and other fungi, estimated by bioassay with *Bacillus subtilis*, are presented in Table 3. Streptomycin contents are expressed on a dry weight basis. The mycelial homogenates of the *Pythium* sp. contained 137–620 p.p.m. streptomycin, whereas the chitinous fungi contained only 2–53 p.p.m. antibiotic.

Mycelial homogenates of both streptomycin sensitive and insensitive fungi were incubated with 50 p.p.m. streptomycin at 37° C, over a *p*H-range of 6–8. No differences in streptomycin content were detected after 72 h incubation. Therefore, the streptomycin-insensitive, chitinous fungi neither absorbed nor inactivated streptomycin to any appreciable degree. These results suggested that streptomycin insensitive fungi do not degrade streptomycin enzymatically in the nutrient media under the conditions of this experiment.

The selective fungistatic activity of streptomycin might be explained by the differences in cell wall composition of the hyphæ of the various fungi studied. The data suggest that cellulosic cell walls are more permeable to streptomycin than chitinous ones.

The *in vivo* antifungal activity of streptomycin against a number of species of *Peronosporales* has been attributed to an effect of the antibiotic on host metabolism rather than the pathogen[8]. The data presented herewith, however, provide evidence that the effect may in fact be a direct one, on the pathogen *per se*.

Additional indirect evidence suggesting that cell wall composition, particularly the cellulose and chitin components, influences antibiotic permeability was presented by Eckert and Tsao[1] and Kinsky[3]. The former investigators noted that the streptomycin-sensitive Oomycetes were insensitive to polyene antibiotics. Kinsky[3], on the other hand, revealed that the mode of action of polyene antibiotic Nystatin was altering the permeability of the chitinous cell membrane of sensitive fungi.

Physiological Specialization in *Erysiphe graminis* DC. in Oats

PHYSIOLOGICAL specialization has been reported in powdery mildew (*Erysiphe graminis* DC.) with f.sp. *hordeae* attacking *Hordeum* species[1] and f.sp. *tritici* on species of *Triticum*[2], but there is no record of such specialization in *avenae*.

In the course of breeding new varieties of oats at the Welsh Plant Breeding Station, hitherto resistant selections of *A. sativa* L. have succumbed in recent years to attack by *Erysiphe graminis avenae*. In an extensive investigation of the sources of mildew resistance available in *Avena sativa* L. and related species, Griffiths[3] established that there were several genotypes with various degrees of resistance, two of which have been used in the oat breeding work at this Station[4]. First, 01747/10/7 derived from a cross between two selections from (Victory × Red Algerian) and (Red Rustproof × Record) hybrids, and secondly, Cc 4146 derived from a natural cross of *A. sativa* × *A. ludoviciana* Dur. The 01747/10/7 resistance was introduced into Manod, and until recently it has exhibited a high degree of field resistance. Observations in the breeding nursery, however, have indicated that Manod has now become susceptible to attack, and reports from various parts of Britain confirm this. At Aberystwyth the immunity of Cc 4146 to mildew was maintained even when the 01747/10/7 resistance succumbed to attack, but during the past 3 years segregates containing the Cc 4146 resistance have also become infected. Plants of *A. ludoviciana* Dur., Cc 4346 and Cc 4347, originally obtained from Miss J. Thurston, Rothamsted Experimental Station, Harpenden, have,

however, continued to be resistant, showing only a slight development of mycelium followed by necrotic lesions when subjected to heavy infection of mildew. This hypersensitive form of resistance has been maintained in segregates from crosses with *A. sativa*, and these are now being used for breeding mildew-resistant varieties. The immunity of the diploid Cc 3678 has also been maintained throughout this period.

Recent work at the Station has shown that the breakdown in resistance of Manod and Cc 4146 is due to the presence of different physiological races of *Erysiphe graminis avenae*. Single pustules of the pathogen growing on Manod and Cc 4146 in the glasshouse were isolated and multiplied on their respective seedling hosts through seven cycles of selection before testing on the five forms of *Avena* listed in Table 1.

Table 1. Differential Varieties of Oats Showing Source of Mildew Resistance

Differential oat variety	Source of mildew resistance
Milford S.225	—
Manod S.235	01747/10/7 *A. byzantina* Koch.
Cc 4146	Natural hybrid *A. sativa* × *A. ludoviciana*
9065 Cn 6/3/74	Cc4346 *A. ludoviciana* L.
Cc 3678	*A. strigosa* sub-species *hirtula* (Lag.)

Seedlings for multiplication and testing were grown in 5-in. pots and isolated in glass cylinders covered by spore-tight muslin. Table 2 shows the mildew infection on a (0–4) scale as defined by Cherewick[5] on the five differential varieties after inoculation with two of the different isolates, maintained at 15° C under glasshouse conditions, and the observations on their field and glasshouse reaction made by Griffiths[3] during 1948–53 (unpublished results).

Table 2. Mean Infection Types (0–4) Scale produced by Three Physiological Races of *Erysiphe graminis avenae*

Physiological race	Host differential varieties: Milford S.225	Manod S.235	Cc 4146	9065 Cn 6/3/74	Cc 3678
1*	4	1–2	0	0–1†	0
2	4	4	0	0–1†	0
3	4	4	4	0–1†	0

* Varietal reactions observed and reported by Griffiths (ref. 3) under field and glasshouse conditions 1948–53, designated Race 1.
† 0–1, very resistant, only slight development of mycelium followed by necrosis of host tissue.

It is proposed that the differential varieties referred to in Tables 1 and 2 be used as a basis for physiological race differentiation in *Erysiphe graminis* f.sp. *avenae* and that the two physiological races isolated in this investigation be accordingly designated as Races 2 and 3 of *Erysiphe graminis avenae*, and the physiological race to which Manod, Cc 4146, 9065 Cn and Cc 3678 were originally resistant as Race 1.

MICROBIOLOGY

Influence of Light on the Biosynthesis of Bacteriochlorophyll by *Rhodopseudomonas spheroides*

Many species of the purple bacteria can grow under conditions of aerobic dark metabolism as well as in the light under anaerobic conditions[1]. Cells growing in the dark contain no bacteriochlorophyll and no carotenoids or only traces of these pigments[2,3]. The apparatus for photophosphorylation which is localized in the chromatophores is also absent in aerobic cultures[4,5]. Transfer of aerobically grown organisms to anaerobic conditions in the light results in the adaptation of the cells to form the pigments and the chromatophores[7]. Partial pressure of oxygen and light are the main factors in regulating the formation of the photosynthetic apparatus in the cells[2,3,6,7]; but we did not know the kind of influence of light.
